In other cases the persistent vomiting subsequent to gastroenterostomy must, I think, be due to a functional cause, the vagus and sympathetic nerve plexuses producing antiperistalsis. In the case of the sixty year old male patient, cited above, it struck me as rather remarkable in the first four days of postoperative treatment, that he had regularly retained every drop of a quart of the usual medicated rectal instillation, administered every eight hours. I am sure the typical observation of operators everywhere is that at least a part of these drips, given three times in twenty-four hours, is expelled on the third or fourth day after the operation. I feel that likely we had to deal with an antiperistaltic action of the lower bowel. Whether this be so and whether the antiperistalsis gradually ascended to the small intestine I am, of course, unable to prove, particularly as a slightly fecal odor of the vomited masses was noticed only later on, when the indication for the introduction of the duodenal tube was found.

It should be said here, that in June, 1917, Dr. Einhorn published a paper entitled The Importance of Duodenal Alimentation in Severe Dyspepsia Occurring After Gastroenterostomy in the *Medical Record*. His observations dealt with the beneficial effect of duodenal feeding in the presence of untoward symptoms occurring, or persisting for, weeks and months after establishment of the anastomosis. Eight out of ten patients treated made a complete recovery, not requiring any further surgical aid. Two others showed considerable improvement during this treatment, but as soon as the tube was removed and nourishment given in the usual way the pains returned. Both had to undergo a second surgical interference.

Here, then, the value of the duodenal tube became apparent in cases manifesting untoward postoperative symptoms of a more chronic type.

The clinical observations exhaustively described above refer to the days immediately following operation. They prove that the duodenal tube may act as a lifesaving instrument by rendering unnecessary the reentering of the abdomen in order to perform either an additional enteroenterostomy—often technically very difficult on account of the short afferent loop—or a jejunostomy.

In a weakened patient, with little power of resistance left, after days of postoperative vomiting, further operative intervention means a serious undertaking in his already precarious condition. If it can be avoided by employing a harmless, though perhaps to some patients somewhat unpleasant, interference, this certainly is the preferable procedure.

At all events, the duodenal tube tides the patient over the gravest time in acute and subacute postoperative vomiting, that does not yield to either gastric lavage nor colonic irrigation, the old socalled vicious circle, now surely rarely met with after gastroenterostomy. And the duodenal tube not only stops the vomiting, but permits regular alimentation and the instillation of quarts of fluid by the rapid drop method.

To my mind the duodenal tube after operations on the stomach deserves to be put to use much more frequently than seems to be the case at present.

A Pollen Filter

Preliminary Report of the Treatment of Hay Fever in Rooms Made Pollen Free by a New Filter

MILTON B. COHEN, M.D.
Cleveland, Ohio

In the treatment of pollen disease there are two available methods, one, the removal of the patient to a habitat where the specific pollen causing the disease does not exist in sufficient quantity to produce symptoms, and second, the production in the patient of tolerance to the specific pollen so that the quantity present in the air is insufficient to produce symptoms.

The first method is impractical for the majority of patients with pollen disease as contrary to the old adage that "Hay fever is a disease of the rich," it is present among people of all financial strata of society. Only the wealthy can afford to go away for a sufficiently long time or far enough to obtain relief, and many of these will not do so as those resorts where relief from hay fever is found are amidst primitive surroundings far from civilization. Weed pollens like the flag, follow closely the advance of civilization and progress. Hence because of financial or social reasons the second method has become the more commonly accepted one.

This method too has its limitations as it is not always possible to establish sufficient tolerance for complete or nearly complete relief from symptoms. Statistics published by a number of observers show that relief is obtained in from forty to eighty per cent. of cases and my own records substantiate these figures.

There is a large group of hay fever sufferers therefore who get little or no relief because of insufficient or unsuccessful treatment.

Last year I had as a patient an engineer whose specialty is dust collecting and conveying. He stated that he could build an apparatus which would be practical for use in the patient's home, which would produce and maintain a pollen free atmosphere in any ordinary room. Early in August, 1925, I received an experimental model of this machine. It was designed to filter out all of the pollen and dust in an incoming air stream and to bring so much pollen free air into the room each minute that a positive pressure of air would be produced and air would leave the room through all the cracks and openings instead of entering through them. The diagram illustrates the engineering principles of the apparatus.

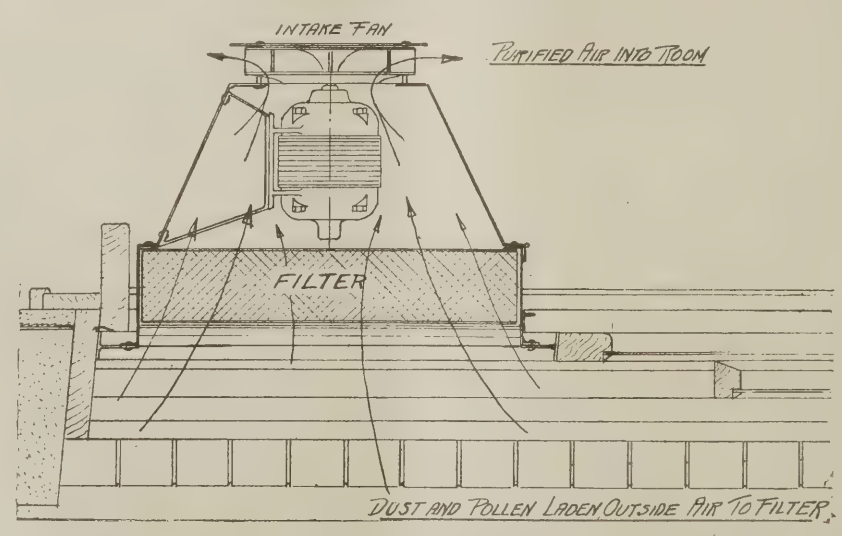

Fig. 1.—Diagram of filter

EXPERIMENTS

The following experiments were performed many times, the protocol illustrates a typical result.

EXPERIMENT I

Atmospheric pollen plates were distributed over the entire area of exit of filtered air. The motor was started and five hundred cubic feet of air per minute were passed through the machine. Then two hundred and fifty mgm. of ragweed pollen was thrown into the air intake of the machine and operation at this speed was continued for ten minutes. The plates were then removed and examined microscopically for the presence of pollen. No pollen was found on any plate.

This experiment demonstrated that the machine was capable of freeing air of ragweed pollen and that it would bring into a room five hundred cubic feet of pollen free air a minute.

EXPERIMENT II

The machine was placed in the window of a hospital room with a cubic capacity of fifteen hundred feet. The door into the corridor was closed and the machine was started. Within one minute a stream of air could be felt escaping from the room through the keyhole and under the door. This current of air had sufficient velocity to blow a cigarette paper several feet along the floor of the corridor. Since the volume of air entering the room (five hundred cubic feet of air a minute) was one third the cubic capacity of the room, the air in the room was completely changed every three minutes. Atmospheric pollen plates were exposed in this room for periods varying from several hours to three days. In no instance was a pollen found. Similar plates exposed in the corridor and in adjoining rooms contained many pollens. This experiment demonstrated that by means of this apparatus an ordinary room could be maintained pollen free when the atmospheric air contained many pollens.

Further experiments showed that this room could be maintained in a pollen free state when the volume of incoming air was reduced to three hundred cubic feet per minute and the air was completely changed every five minutes. During these experiments nurses and doctors entered the room through the door whenever necessary for the performance of their routine duties, the only precaution being that the door was opened and closed slowly.

When patients were placed in this room a number of interesting observations were made.

1. Patients with hay fever without asthma noticed some relief within a few minutes, and after from six to eight hours the nasal and ocular symptoms were completely relieved.

2. Patients with severe ragweed asthma required from two to five days before their acute paroxysms subsided. This observation was at first disconcerting as it was contrary to our expectations. However it was soon remembered that pollen could not be absorbed until acted upon by the ferments of the tissues with which it was in contact. There is very little known about the rate of decomposition of this pollen or the rate of absorption of its products. It is not improbable that it requires two to five days to absorb and neutralize the dose of pollen present in the respiratory mucous membrane when the patient is placed in the pollen free room.

These problems are being studied and further reports will be made from time to time.

SUMMARY AND CONCLUSIONS

An air filter has been devised which will completely remove pollen from the air.

By means of this filter it has been found practical to maintain rooms pollen free during the ragweed pollinating season and to study the speed with which patients become symptom free when removed from pollen laden atmosphere.

During the coming vernal and autumnal hay fever seasons the use of this machine in the prophylaxis of pollen allergy will be studied. Machines will be placed in patients' homes and offices so as to simulate as far as possible seasons of the year when there is no air borne pollen.

A RARE MISHAP IN LITHOLAPAXY*

Louis Neuwelt, M.D.
New York

A man, aged forty-five, complained of suprapubic pain on urination and a sudden stoppage of the urinary flow. A litholapaxy was done sixteen years ago. One year ago he suffered with typical renal colics, when roentgenography revealed three small calculi in the ureter, which were manipulated into the bladder. They are not known to have been passed spontaneously, nor was any attempt made to remove them.

Recently a cystogram showed an ovoid shaped stone about as large as a fair sized plum. Cystoscopically it appeared to be of phosphatic consistency. There was no other bladder abnormality visible.

As the patient absolutely refused a cystotomy, litholapaxy was advised and undertaken. During the procedure of stone crushing a metallic click was felt and heard and on removing the lithotrite, the male crushing jaw was found broken off at its junction with the shank. A Bigelow evacuator with a straight catheter attached was introduced and the broken fragment, measuring about three-quarters of an inch was aspirated.

This embarrassing mishap is an extremely rare occurrence, as evidenced by a review of the literature. The instrument was a product of one of the standard manufacturers, who claimed that the accident was the result of a faulty technic of manufacture.

Aneurysm Treated by Wiring.—G. H. Colt (*British Journal of Surgery*, July, 1925) reports three cases, one his own, which lead him to affirm that it is now clearly proved that the dull gilt wisp is sufficient to initiate active clotting in a saccular aneurysm even in an actively syphilic patient, and that it is unlikely to project through the opening of the sac. The wires do not become dissolved or broken, and appear to cause no trouble after many years. It would appear that the employment of electrolysis is not essential to start the clotting, and the experiments of Dawson Turner amply confirm this. If electrolysis is employed, he recommends zinc as the electrode. Macdonagh may be read in this connection. A simple way would be to coat alternate strands with zinc.

*Reported at a meeting of the Clinical Society of the Jewish Memorial Hospital, January 5, 1925.

Historical Medicine

Ancient and Modern Medical Heresies

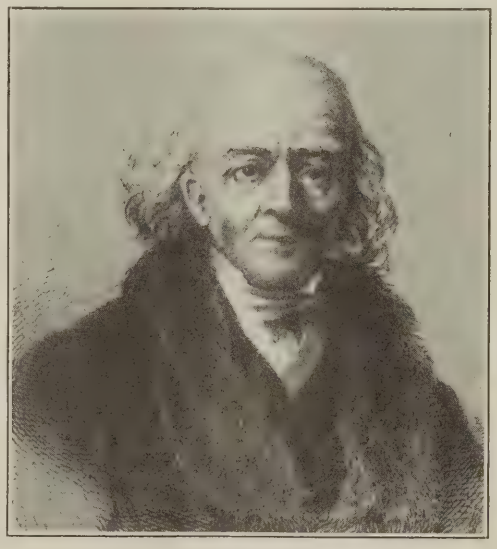
(I) *Homeopathy and Christian Science*

JONATHAN WRIGHT, M.D.
Pleasantville, N. Y.

My interests have lately led me to a more careful reading of the text of Galen's remarks on the theories which interested Plato and Hippocrates, which fill more than six hundred pages of the text and translation of Kühn's edition (1a). It is a glaring deficiency in our literature of the history of medicine that there exists no translation into English of Galen's works, no good modern annotated edition of him at all. By far the most accessible and convenient and on the whole the least objectionable is the Kühn Latin translation, more or less closed to modern readers, with the accompanying Greek text. The Latin translation is often, how often I do not know, taken from older works. Whether Kühn's rendition or not, errors and inaccuracies and obscurities abound. The text is printed on abominable paper, but the Greek part though with miserable type is apparently freer from errors and inaccuracies and is far less obscure than the Latin translation. At least this is the impression of one in no way an impeccable critic himself.

Galen, though often long winded and sometimes on that account wearisome, is never dull and I have been amused in this treatise of his to observe the indications of how similar were the heresies assailing our profession in the days of Hippocrates, in those of Galen and in our own. In the recollection of men still living, who can look back fifty years or more, the three sects arising outside the pale of the profession which in that time have most exercised the imaginations of men, most taxed their patience and made the largest drafts upon their charity—drafts for the most part not honored we reluctantly admit —have been homeopathy which fifty years ago had reached its summit, the mind curists and the chiropractors, of more recent origin. During the early years, the middle years and the later one sect or other at one time or the other has aroused alike a sentiment in the breast of the regular practitioner for which only one name is descriptive—detestation. As time has rolled over each term of that epoch of a half century grudgingly, slowly, with halts and hesitation, the medical profession has opened its doors and allowed to slip in, if not the individuals much of the essence of the doctrine of infinitesimalists, of the Christian Scientists and lastly the rubbers are now knocking, if not at our doors, at the doors of the legislatures. The homeopaths have entered them and have lost their identity chiefly because we have all lost about as much faith in drugs in that time as we had in phlebotomy before it. Both drug therapy and phlebotomy may be said still to exist, but it is largely due to the homeopaths that drugging a l'outrance has practically disappeared and very much of the faith existing fifty years ago in any drugging at all.

I well remember as an interne in a hospital counting the prescriptions of one of the attending staff, a very acute diagnostician and by far the best educated man on the staff of a large metropolitan hospital. One patient was taking on one day eight prescriptions and a new one was pretty sure to be added the next day. Time and room for it in the patient was only secured by the house staff surreptitiously crossing off the oldest one. The faith curist and the mind curist have aroused the activities, inimical but receptive, of the psychiatrist, and the chiropractor and the massaseur have similarly influenced the physicotherapist in the regular profession—given birth to them one might almost say, but it is only the wise child among them who recognizes his father. For these are despised and maligned rivulets wandering in the waste of error, headed in the wrong direction, which have fed and mightily influenced the clinical practise of medicine in our day, without adding very much of value after all to the great onflowing stream of actual knowledge and the guiding theories by which the main current is directed. But they belong legitimately to the history of medicine. The high contagion theories have come off their perch, the fresh air fad is starting for the limbo of oblivion where has rested that of Athens for twenty-five hundred years and at which Aristophanes mocked at the time.



HAHNEMANN

EARLY HOMEOPATHY

As long ago as that the minds of men had flitting through them the infinitesimals of Democritus, if not infinitesimal doses. If they had no way of making doses infinitesimal they were well acquainted with the doctrine of similars, the *similia similibus curantur* of Hahnemann, for had not Empedocles declared the affinities of similars to similars as Alcmaeon, his master before him, had been busy with antagonists and the equilibrium of health between them? Even Hippocrates and Galen agree our bodies are made up

of earth and water and air and fire and that on account of the lack or excess of these or their misplacement diseases arise (1b). Now Nature is a great restorer. The *vis medicatrix naturae* is the sheet anchor of therapy yet, which we have heired from Hippocrates, whose therapy Asclepiades derided as the "contemplation of death." It has been the sheet anchor, however, of every sensible practitioner since. When there is a deficit of water Nature demands moisture, the feverish man demands drink. God forgive me for bathing all my typhoid patients in ice water but forgive still more generously my medical forefathers for snatching water from hands trembling with fever and thirst and hunger. When I was a student Dr. Alonzo Clark selected from medical history in 1880 his favorite joke. "Graves fed fevers." He went on to explain this was what Dr. Graves, the talented Irishman of the early part of the last century, wanted put on his tombstone. "The idea then was and still is now in your time, young gentlemen, that fever feeds graves, because we do not feed fevers." Alas, I have forgotten how Dr. Clark fed fevers, but I know we allowed the poor devils only to get a glass of milk every two or three hours for more than a score of years after that old joke first became known to us, not noticing Nature was begging for something more substantial.

DECLINE AND FALL

Well, when the trouble was with the moist element of the body in disease it was water you wanted to give or take away. *"Similia similibus curantur,"* the old dialectitians and diatitians had a great time as to just what they meant by that, whether it was a theory of deficiency or of a repletion of the element. They ended up with taking it away in fevers. Alcmaeon balanced deficiency against repletion and saw health in the centre, but nobody but a dyed in the wool dialectitian ever thought this meant anything. Like everything else in life with which man comes in contact there is a balance of good against the evil. It was Heraclitus taught that and at Ephesus he imbibed it doubtless from the same source as the Zoroastrians who made a religious theory out of it, a spirit of good in continual conflict with a spirit of evil—for a man's soul as the Christians and Dr. Faustus found out. Now it was Empedocles, who had been a pupil of Parmenides of Elea and who added the doctrine of similars to that realization of the old Nature Philosophers after Heraclitus which made this world a conflict between Ahriman and Ormuzd, between good and evil. It was Empedocles who first introduced into the physiology of man this idea of similars which had such a career until it disappeared in the materialistic and skeptical bosom of medicine.

METABOLIC DISEASES

I have just alluded to the natural doubt of the clinician in the case before him, after he has settled it that the trouble is with some element, water or the bile or the internal secretions—or God knows what is liable to appear as a factor in disease before this script is published—whether the patient is suffering from a repletion or a deficiency of water or bile or vitamine. Quite evidently the major argument for homeopathic doctrine gets in a blind alley here. If a man has dropsy, too much water, the ancient doctor could hardly expect to cure him by giving him more water or increasing his bile when he was bilious. The *similia similibus curantur* must be worked by getting rid of the water or the bile. Well in ancient medicine as in modern there was a factor in disease which might be ascribed sometimes to repletion and on the other hand a deficiency undoubtedly lies at the bottom of other maladies. Medicine came to Greece largely from Egypt, the land of plenty—for the rich—and it was food, too much of it, caused the trouble and a man should be purged regularly once in so often any how, whether he had anything the matter with him or not. But in the sterile land of Greece torn by wars and famines, this notion met with an opponent. Under the scourge of the European wars in Hahnemann's day and in ours the mortality of deficiency diseases arises. Starvation has a number of poor kindred—"poor blood," consumption, rickets, reduced resistance to infection. Whether food or drugs the system craves addition to its forces, "Give me more fat, more blood, the earthy in my bones cries for more iron." *"Similia similibus curantur"* has a career in this crude train of thought and we may be sure it was not absent from the teeming brain of the ancient Greek. The Egyptian liver had its plutocratic trouble, as did that of the English nabob in India and the Nile doctors pointed it out, but Empedocles and his friends along the north shore of the Mediterranean had other tales to tell.

HIPPOCRATES

Hippocrates knew what he was talking about when he wrote his *Airs, Waters and Places.* He knew well how much these influenced the diseases as well as the character of men. Their influence upon the history of thought has not had the consideration it has had in the history of man's social and political life and it has had little enough there. If it had had more attention from statesmen, socalled, they would not have been so eager to feed the southron on the Nordic meat broth of democracy. The doctor, like his master Hippocrates, quickly finds out that health rules differ in Siberia from those in India and the theories of medicine in the history of thought must be viewed with an eye prompt to note the weather. As we cross isothermal lines from the equator to the pole it is not alone the habits and the color of the skin of man that changes, but the color of his thoughts also.

Nevertheless whatever may be the variation in things variable, there are some fundamentals of thought which do not change with airs, waters or places or time. Deficiency and repletion, the doctrine of opposites and the doctrine of similars and the doctrine of equilibrium are not altered by latitude or longitude. The intellectual problem which interested Empedocles in Mediterranean airs twenty-five centuries ago interested Hahnemann a hundred years ago among the Hyperboreans. The propagation of the thought of each resulted in much cogitation on the details of the philosophy of each epoch and each latitude. It affected the outlook of medicine in each age.

We have taken the homeopaths into the sheepfold again; how much of their doctrine of similars with them I cannot say, but it seems clear at least

that their infinitesimals have knocked out the calomel and jalap debauches of our forefathers.

GALEN

A year or two ago I ran across Christian Science in Galen (1c), or at least that is the heading under which what I had to say about it appeared in these columns (2). In Kühn's Galen it is "ascribed" to him, but it seems to me there is every reason against ascribing the treatise in which I found it to him. It is probably by some later writer, who for the moment broke away from the hot and the cold, the dry and the moist and the crass materialism of medicine, from the similars and the antagonists, and took refuge, when other things failed him, in the influence of faith or the mind on disease,—in the mysteries we are apt to believe in because there is no good reason why we should. "Why then," he asks after citing experience, "why should Christians fail to make use" of this belief? Why indeed? It was not Galen wrote this for he was no Christian, so far as we know, but in this discourse of his on the theories of Plato and Hippocrates he occupies a good deal of space (1d) in quotations from Chrysippus and Posidonius and still more in his own pungent remarks on their opinions. Plato before them, in the temper of a philosopher, had discussed the question whether infirmities of the mind are to be compared with deformities of the body or not. He thinks there is in many ways an analogy between them, but he did not go to the limits which excited the impatience of Galen. He falls upon Crysippus just as though he had not been dead several hundred years and covers him with objurgations and ridicule.

CHRYSIPPUS

Chrysippus was born at Soli or Soloe in Cilicia over against Cyprus on the mainland of Asia Minor, where they spoke poor Greek and whence the term solecism is derived. How much of oriental philosophy he absorbed before he went when still young to Athens can not be said, but there he evidently was put through a course of sprouts in Greek grammar from which he never recovered for a large part of his thought seems to have been engaged in knowing and teaching how one must pronounce words. However Attic his Greek became the extracts we read in Galen from his works seem to smack of the orientalism at his back when he was young,—not least his leaning toward Eddyism across the ages. From the long quotations,—for none of Chrysippus' work itself has reached us,—we gather he believed the diseases of the body should be treated on the same principles as diseases of the mind and that in the cure of the former the state of the mind was a large factor if not the largest factor. Thus far he appeals to us, but Galen is in as much of a pet about Chrysippus as we are about Mrs. Eddy, who is dead also. Plato earlier and Posidonius later laid much stress upon this more reasonable side of the question, but Galen, whom we often suspect guilty of misapprehension or even of misquotation and of downright lying on occasion, quotes sentiments and theories from Chrysippus which are of the same nature and quite as absurd as any I have seen quoted from the late lamented lady, whose churches are crowded with former occupants of other temples of worship, now empty, and with many who never before saw the inside of a church at all. The psychiatrists and psychical methods of cure crowd our modern temples of Aesculapius about as much.

EARLY FAITH CURES

However much we may disagree about the influence of cults outside of medicine on medical practice and theory it would seem that the ancient men of our cloth were well acquainted with the influence of such environment. It seems from the record in Galen (1e) Chrysippus got his ideas through Epicurus and Zeno of Citium, for disease according to their doctrine is largely, dependent on what is thought desirable and what is to be avoided. Something of the idea has had, how far back I do not know, a crystallization in the old joke. "She enjoys constant bad health, thank you." Variations in health and disease (the kind of disease we are familiar with as amenable to the mind cure treatment?) are due to the rise and fall of irrational impulses or fancies, but Chrysippus seemed to separate disease from fancy and Galen impatiently and scornfully remarks: "Just as though a man reasoning falsely *needs* to be distinguished from an animal or a stone void of reason." That kind of thing is not so devoid of symptoms it can not be recognized,—it is not a thing overlooked by investigators,—it is a force of the soul disobedient to reason. This tendency to carry the thing too far does not come out to meet us in the works of Plato and the opinions of the earlier philosophers, but in Chrysippus who, after Zeno, took his place at the head of stoic philosophy in Athens, we plainly see the germ thought of the mind cure and faith cure three hundred years before Christ and five hundred years before Galen.

BACK TO ZENO

Through the critical mind of Galen and his sharpened wits we penetrate back of Chrysippus to Epicurus (342 B.C.) and finally, as with all philosophy that is worth while, Plato (428 B.C.). According to the given chronology, an exceedingly weak reed to lean on, Chrysippus (b. 280 B.C.) may, as a boy of 16, have seen Zeno (d. 264 B.C.) when he was very old, but he could hardly have had much of his wisdom from his lips. So far as chronology goes however in this case it is indicative that as early as Zeno at least such theories of disease—and this is essentially a stoic tenet—must have pervaded Athenian thought.

Bismarck and Medicine.—Bismarck ran through twenty-nine physicians before he at last came to Professor Schwenninger, who succeeded in reducing his fat. The result was not achieved without much personal friction. Schwenninger, in his first interview, pestered his patient, the Iron Chancellor, with so many questions as to his habits of life that at last the prince lost his patience and said, "You ask me too many questions."

"Very well," said Schwenninger, "you go to a veterinary surgeon, as he won't ask you any."—*London Evening Standard.*

David Hayes Agnew*

An Estimation

JOHN B. DEAVER, M.D.
Philadelphia

It would be an alluring pastime to picture the elect of a former day returning to the sphere of their activity and viewing the vast changes that had taken place since they had ended their earthly sojourn. The great doctors among such spirits would certainly be impressed with the methods in vogue, the various refinements of, and adjuncts to diagnosis and treatment, the bewildering multitude of specialties and the wealth of associated branches of their art. They might possibly look with envy on the opportunities for study and practice of which they scarcely dreamed and which if they had had might have added to their own efficiency and glory. But one cannot help wondering whether their admiration and perhaps their envy would not be tempered by a certain degree of pride in what they were able to accomplish with the simplicity of equipment with which they worked depending mainly on the training which enhanced their own natural gifts and senses.

Prominent among such spirits would stand the master surgeon, the inspiring teacher, the loyal friend, David Hayes Agnew. Although in the later years of his career he was privileged to enjoy some of the advantages of modern surgical procedure, and indeed was among the first to adopt the newer ideas of antisepsis and asepsis, his early training covered the pre-Listerian methods.

In honoring his memory this evening we are doing honor only to ourselves. To me, then, it is a double distinction to have been assigned the privilege of recalling some of the characteristics of this towering figure in the medical world both to those who may have known him and to a younger generation that knows him only by tradition.

The world at large sets up its ideals for every walk in life. It probably has a loftier conception with regard to what constitutes the ideal physician than appertains to other professions. The reason for this is not far to seek. For to none other is it given to have an individual, in his hour of greatest need, place himself so confidently in another man's hands. With whatever force this may apply to the physician, its meaning is increased to the utmost degree where the surgeon is concerned. Dr. Agnew met this demand as few others have done.

To the youth of his day, who were fortunate enough to come under his personal influence, no less to the patients, who came under his ministrations, his presence was dignified and inspiring; his conduct at the bedside direct and to the point and withal sympathetic. This direct earnestness in the class room brought him the respect, admiration and love which remained with his students and colleagues throughout his life. All these traits were but the reflection of what was perhaps the outstanding characteristic of Agnew as a man—the devout, loyal, faithful Christian gentleman. The sincerely religious faith of this man of science spread its halo around his every act and hallowed the name of surgeon as a real healer of the sick.

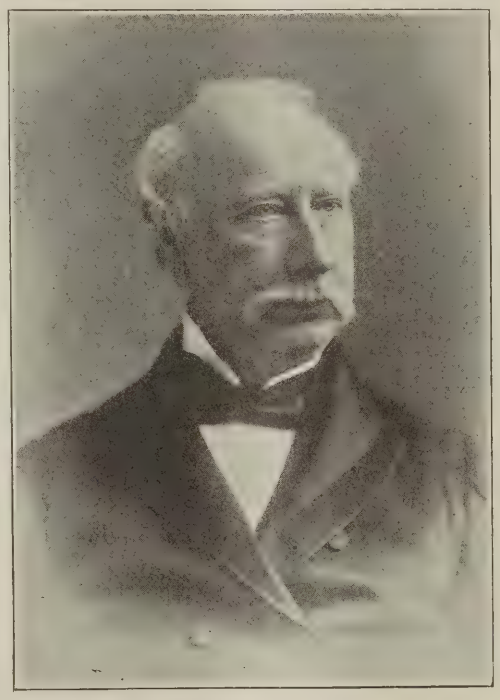
It was as a teacher that his personality was at its best. He was impressive because of his simplicity—simplicity borne of complete command of his subject. His language was clear and concise and could not fail to make his explanations of the most difficult subject comprehensible to those who sat at his feet. His mastery of his subject was the result of years of painstaking study and dissection. In these days when surgery is so attractive to the budding doctor that in his dreams the road to mastery appears a short and direct one, it is well to remember that what made Agnew the master-surgeon were his love of the work, tireless industry and marvelous patience carried on through years of preparation. Early he realized that anatomy is the mother of successful surgery and was convinced that to become preeminent in his profession a surgeon must needs spend a number of years in the practical demonstration of anatomy. These principles were the basis of his greatness and the facts of his life exemplify his theory.

Agnew's determination to become a surgeon came after his early professional career had been interrupted by the allure of a business venture, into which, for family reasons, he felt obliged to enter. Fortunately for the realm of surgery, the venture proved unsuccessful and he eagerly resumed his medical career, the love of which was part of the very fibre of his being.

For a short time he practised in a country village, but in spite of a growing and successful practice, his early dream of becoming a surgeon dominated his thoughts, and he set about to realize his ambition. Securing his anatomical material from Philadelphia he began to study and dissect in the privacy of his own home—established a laboratory of anatomical research would be the sonorous term applied today to this modest beginning of a brilliant future. Surrounded by narrow minded village gossips, his work naturally aroused the suspicion of his neighbors. Unable to dispel the doubts and distrust and to quell the criticisms which his studies aroused among the villagers, he determined to endeavor to satisfy his aspirations in more congenial surroundings. Unheralded and unannounced he came to Philadelphia where he began his career in that unique and interesting institution, the Philadelphia School of Anatomy. It would be carrying coal to Newcastle, I fear,

*Read before The College of Physicians of Philadelphia, December, 1925.

to launch into a description of this famous school, but an audience like this are especially interested, as it is in the annals of medicine, of which that school is so integral a part. There is little doubt that it was a tremendous factor in establishing the early fame of Philadelphia as a Surgical and Medical Centre, for its list of demonstrators and teachers comprises names to conjure with in the world of surgery. For ten years Agnew was the responsible head of this school. It is in the experience gained during these years wherein lies the secret of much of his success. His dissections were made always with the idea in mind of their practical application for the operating surgeon. He worked for the love of the work. He was as unaffected by the fact that his early classes consisted of only nine pupils as by the circumstance that through his personality and charm as a teacher, the gradually increasing attendance demanded the gradual addition of assistants to the number of five. He was not discouraged by the first, nor unseemingly boastful of the second. Steadily he continued his work, meeting his students each winter for 130 evenings "to discuss the high theme of God's masterpiece of handiwork." In addition to the demonstrations in anatomy, he also conducted the School of Operative Surgery where a special class was held for demonstrations of surgical anatomy of the different regions, illustrated with drawings, the skeleton, and wet and dry preparations, the course being conducted until all the operations feasible on the cadaver had been done. The students for these classes were not confined to any one school but came from the University of Pennsylvania, the Jefferson and Pennsylvania Medical Colleges, and the Dental Colleges. Adams, Agnew's biographer, has well ascribed "the secret of the grace, ease and sureness with which Agnew operated as being due to his perfect knowledge of anatomy which he learned in this school. He never had to stop to think out answers to questions in regional anatomy. He reached his conclusions as quickly and as naturally as if he were reading an open book, which justified the statement that he seemed to see the positions and relations of the internal organs of the body as well as if their coverings were made of glass."



DAVID HAYES AGNEW

In 1862 Dr. Agnew gave up his work in the anatomical department of the school and in the following years his courses in operative surgery to become demonstrator of anatomy and lecturer on clinical surgery at the University of Pennsylvania. This transfer of his activity was but a change of environment, for his service here was marked by the same earnestness and the same conscientious, untiring devotion to the work of the hour and the same consideration for the needs of the student as it had been in his earlier experience, in spite of the fact that for seven years he occupied the subordinate title and position of demonstrator.

Although he had come to the university with a reputation well established it was not until 1871 that full recognition was given his extraordinary talents, and then only after his threatened resignation did the university accord him the place he merited in the faculty by re-creating the chair of professor of clinical and demonstrative surgery and making Agnew its incumbent. This recognition came after thirty-one years of active professional life. Young men of today take note!

This acknowledgment might have come to Agnew sooner had his been an aggressive personality. But his imperturbable and calm outward demeanor was a true reflection of his innate tranquillity of soul. To those who knew him personally it was this gentleness of soul that made him the well beloved teacher, friend and medical counselor. It was also a great asset in his work at the operating table, which is well delineated in the familiar painting which graces the walls of the University Medical School.

There is no doubt but that a born surgeon, such as Agnew was, would have made his mark in the profession at any time, nevertheless a fortunate circumstance in his career was the rise of modern methods in surgery which he was among the first to adopt. It was, of course, not at all surprising that he who in his youth had had the temerity to begin his anatomical studies amid hostile surroundings should in his riper years adopt what, with his clear and intelligent vision, he realized as the greatest opportunity that had as yet come to the surgeon.

It is a pleasure to recall his entrance into the operating room. Tall, dignified, tranquil, he approached the operating table with inspiring confidence and yet with a certain amount of modesty. His manipulations were deliberate and deft to a degree that is granted to few. Some of his unusual deftness has been attributed to the fact that he was as clever in the use of his left hand as of his right, working with the one or the other quite unconscious of which he was using; but there is no doubt that the greater part was due to his remarkable delicacy of touch together with an almost unfailing sureness gained by his unusual training as an anatomist and his wide experience in practical surgery gained in diverse hospital and private practice and in his service during the Civil War. For a man of his extensive experience and as busy a man as he was it would be almost natural to develop a routine habit of thought and action, that would have closed his mind to newer avenues but such was not the case with Agnew. His adoption of

modern surgical procedures was but the beginning of his continued keeping abreast with the times, although his modernity was always tempered with a judicious conservatism.

Fortunately for the world of surgery Agnew placed these qualifications of the surgeon together with the results of his vast experience at the disposal of students and surgeons, not only by his masterly work at the operating table, which those who were fortunate enough to witness can never forget, but also by his master work on the *Principles and Practice of Surgery,* the three volumes of which form a compendium of his daily professional life for fifty-one years. Its pages breathe his personality and even to this day their contents have retained much of their value. His views on surgical diagnosis will bear repetition at this time when the refinements of diagnosis are so dangerously near crowding out the training in the natural methods the use of which stamped men of Agnew and his generation with their greatness. In the introduction to his surgery we read:

"Anatomy, physiology, organic chemistry, and physics form the ground work of diagnosis. For the proper interpretation of morbid phenomena the senses must be carefully educated and the mind trained in the precise logical methods of thought. There is a very great difference in the rapidity with which different men, of unquestioned surgical ability, form their judgments on the nature of disease or injury. There are some who reach their conclusions with a celerity which resembles more an intuition than an orderly process of deductive reasoning; while others pass over the same ground like the prudent general who fortifies every captured post as he advances into the enemy's country. On the whole, the latter are those who meet with the fewest defeats."

Agnew was not only a great surgeon, but had he chosen internal medicine as his specialty he would doubtless have achieved equal fame in this branch. He was a good physician and general practitioner, and it was his experience as such that influenced his attitude in deciding for or against surgery in a doubtful case. Conscious as he always was of his responsibility and conservative to a certain degree as was his nature, he was always glad if he could see a way of serving the best interests of his patient without the use of the knife. Let his own words express this attitude:

"Whenever the surgeon is compelled to proceed on data of probabilities, it is in most instances a good rule to *wait.* Often in my professional life, when in a maze of doubt and uncertainty, have I imitated with the happiest results the storm-bested mariner, who, in the darkness of the night, and nearing an unknown coast, casts anchor and waits for the day. A few hours of delay may open a crevice in a hitherto hidden case of disease which will be sufficient to illuminate its obscurity and resolve all uncertainties."

But when once the decision to operate was made he was fearless and unhesitating, at once a delight and inspiration to those about him.

The best proof of a man's worthiness, and especially is this true in the medical profession, is the estimation in which he is held by his colleagues. Of Agnew it may be said that he belied the fate of the prophet in his own country. The completion of his fifty years of professional activity was made the occasion of a spontaneous outpouring of the love and esteem which he enjoyed among his professional brethren. The banquet arranged for the occasion was planned entirely without his knowledge. The memory of it to those who were fortunate enough to have been there still lingers as a most happy, impressive and brilliant event. On this occasion, as throughout his life, his modest manner was significant. It is this modest and unassuming manner likewise which has made my task of injecting the personal strain into these remarks a difficult one. His influence was so subtle that almost unconsciously one absorbed it and made it part of one's own life. It is this trait of modesty that also adds difficulty to the otherwise light task of estimating Agnew's influence on American surgery. As physically he towered above most of his fellow men, so professionally he was a giant among giants. But this gigantic scientific importance takes no account of his influence in a personal way on the very large numbers who while learning from him the simple and yet intricate language of surgery, at the same time received the lessons which were to leave their impress upon their character as well as upon their conduct in the pursuit of the profession which he termed the highest and noblest that a man can choose for his calling. As he admonished his students on the occasion of his last lecture to this class, so it may be said of him that he truly aimed and succeeded in elevating his life and rounding it off "in the fullness of an undeviating regard for duty and high purpose." In short, he was "a good man and true, a good physician and a pure and good and honorable citizen."

The Popular Teaching of Child Welfare in France.—In 1860 a Paris doctor named Carron invented the word *puericulture,* meaning simply the rearing of babies, or what we now call postnatal child welfare, writes Dr. L. Devraigne (*World's Health,* September, 1925). He had the idea—a bold one at that time—of giving a course of lectures on baby welfare to mothers of families. It required nothing less than the intervention of an important minister, Victor Duray, to obtain the necessary permission, but the word alarmed and shocked the narrow minded, with the result that the lectures were not a success, and, worse still, the word fell into disuse.

In 1892 Pierre Budin introduced into his department at the Charité in Paris the first baby welfare clinic, which one of his pupils, Dr. Henri de Rothschild, later renamed the School for Mothers. At about the same time the milk centres of Variot and Dufour de Fécamp were inaugurated for the distribution of good sterilized milk. Since it was possible to affiliate these baby welfare clinics with all charitable organizations for mothers, they were quickly adopted by maternity clubs, mothers' canteens or free restaurants for nursing mothers, and later by lying in homes and maternity hospitals.

The other side of child welfare—careful watching of the development of pregnancy—has been emphasized by obstetricians since Tarnier, who in 1875 demonstrated the value to pregnant women of a week's strict diet for preventing difficult labor. In 1877 Pinard laid down the rules for the regular and systematic examination of expectant mothers.

Editorial Articles

LONGEVITY

In the *London Times,* 1925, there were reported the deaths of 352 persons of over ninety years of age. Of these 104 were men and 278 women; of the latter 153 were married. The number of those who reached a century was twelve; of these only one was a man, the eldest being a married woman of 104. Ten others, one man, were ninety-nine. Besides the above named, 109 attained their ninetieth year. The number of nonagenarians whose deaths have been reported in the *Times* during the past eleven years is 3,535, the great preponderance being females, of whom a very large majority were married. The centenarians for the same period number sixty-seven.

The oldest freeman in the United States in 1925 was 107, as also was a lady who died during March in Nova Scotia. The senior man in Canada lived to be 108 and died in June. But "the pride of place" in 1925 must be allotted to Charlotte Nava, who died near Pau, aged 110, of whom it was stated that she had been a servant in the Bovis family for ninety-eight years. She had never had a serious illness.

The first census of Persia, which has just been completed, reveals an unusual longevity among the peasantry of the country. In one village at the foot of the Alwand Mountains lives a woman by name Mina, who is 146 years old and has a son 117. It is stated that these hardy mountaineers, living in extreme poverty in ramshackle huts, live principally on bread and milk, with meat a rare article of food.

THOSE COMMON COLDS

Common colds are common enough, for, according to the Public Health Service study, not more than ten per cent. of us are immune, and each averages about two attacks a season. Whether we be rich man, poor man, beggar man, thief, about forty per cent. of our annual, housed up sickness and loss of time from work is due to respiratory diseases of some sort among which colds are predominant. Despite efforts to teach us to the contrary, those who work out of doors, as delivery men, telephone linemen, etc., have more sickness and loss of time from these causes than those who work indoors.

If we were to continue with our jingle, we believe the doctor, with all his exposure, would be found to have no more cold than the lawyer, merchant, or chief.

Henry M. Warren, in a delightful historical address, reminiscent of Portsmouth, N. H., published in the *Boston Medical and Surgical Journal,* tells how, in the good old days, in that city the "flower of youth and beauty" of Portsmouth were congregated in May and June at Shapleigh's Island to be inoculated with the smallpox. "The majority were perfectly well, and made of the affair a holiday festival of the gayest description." "These parties were made social gatherings and people spent a summer month in this manner instead of going to a watering place."

Until proud "science" in the form of some new Jenner (bless his real name!) comes down from measuring the stars or up from antagonizing atoms or investigating the mentality of parameciums and invents some way of preventing our most common ailment, we do not see but that the happiest solution of the problem would be to emulate the example of our forefathers and mothers and make a social event of this cold taking. We could gather together in up to date undress, with wet shoes and stockings, jazz a bit, and sit in a cold draft thereafter, chatter intimately, cough and sneeze communally, and otherwise lead a natural life. We could then top off the cure with hot lemonade (since the stronger remedy is now too expensive and dangerous), rest between blankets for a couple of days and then go about our business, knowing we were safe for some three months, when a second "cold party" would be the appropriate social event of the day.

What an array of medicinal cures we have had to prove the ineffectiveness of them all! Does anybody now prescribe rock candy with or without whisky, or is it known at all to the present generation? Is Dover's powder still prescribed? We have not heard of it for a coon's age. Perhaps the finishing touch was put to Dover by Harrison?

STATISTICS OF CANCER

It is asserted by some statisticians that cancer is greatly on the increase, while others contend that the increase is but slight. It has become almost an article of faith to believe that cancer is both alarmingly prevalent and the cause of a continually augmenting number of deaths. The report therefore issued recently from the statistical bureau of the New York Metropolitan Life Insurance Company is refreshingly encouraging. This report of a most careful statistical inquiry into the prevalence of can-

cer, covering a period of fourteen years, states that while cancer has increased it has not made the rapid headway with which it is credited by many students of the problem. Dr. Louis L. Dublin, the chief statistician of the company, and his assistants give the most reassuring report of the cancer situation which has ever been given. It is reassuring because it is both comprehensive and analytical. In the opinion of the authors the increase in cancer has been small, much smaller than might be inferred from analysis of the published crude death rate.

More accurate diagnosis, no doubt, has something to do with the increase or apparent increase, although it has been stated recently that a large number of postmortems on cases reported as cancer have proved that the disease was not malignant. However, more accurate diagnosis has brought about the recording of cases which a few years ago would not have been detected. Another reason for the increase is the lengthening of the span of life, cancer being notoriously a disease of advanced age.

One of the most interesting points brought out by Dr. Dublin and his coadjutors is that the increase, such as it is, has been confined almost entirely to males. There has been little or not increase among women, although the death rate from this disease has always been higher among women. Another point is that the white race is more susceptible than the colored.

On the other hand, certain forms of the malady are more fatal to one race than to another, and it has long been known more fatal to one sex than to another.

So far as race is concerned, the Russian immigrants seem most susceptible, the Irish next, and the English, Scotch and Welsh in order next. The Italians are an exception, the cancer rate among the Italians being less than that among native born Americans. At first thought, this difference might appear to be a question of diet, the Italians being largely vegetarians, or, at least, small meat eaters. But Dr. Dublin goes on to point out that according to the conclusions come to by the company's statistical analysis, the cancer rate increases as we go down in the economic scale. If this be so it appears to show that cancer is not stimulated so much by overeating and luxurious living as by a faulty diet. This may be explained to some extent by the fact that the diet of the poor urban population is largely canned food and food of a nature not so nourishing and digestible as that obtainable and eaten by their more prosperous brethren. Such a diet, by its indigestibility, might tend to irritate the mucous lining of the gastro-intestinal tract and at the same time, by its innutritious character, release the body's powers of resistance. These two conditions, local irritation and lowered resistance, cancer authorities state are the most frequent factors in the causation of the disease.

The report states that between the ages of thirty-five and fifty-five, it is probable that there has been an actual decline in the percentage of women who died from cancer, and no increase in the percentage of men. This it is thought may be due in part to the campaign of education carried on during the past decade, and to the number of lives saved or prolonged by early surgical intervention.

While the report referred to is encouraging, it will not do to lapse into a fool's paradise and relax our efforts to conquer the disease. Cancer stands high on the list of deadly diseases and is in many ways the most loathsome and terrible scourge of the human race, and especially of the civilized human race. Every means should be put forth to prevent it; perhaps the day is not far distant when it will be possible to immunize against the disease. At the present time our main hope lies in early diagnosis and early surgical treatment, aided when necessary by x rays or radium. To this end efforts to educate the public as to precancerous symptoms or early symptoms of cancer should be redoubled.

ACTIVITIES OF THE PUBLIC HEALTH COMMITTEE

The Public Health Committee of the New York Academy of Medicine has recently published a summary of its work during the year 1923, which bears witness to the wide scope of the Committee's activities and the definite benefits resulting from them. The largest single piece of work of the year was a survey of existing facilities in New York City for promoting child health, a study made possible by a grant from the Laura Spelman Rockefeller Memorial. One of the significant findings of this survey was the fact that much uncorrelated work is being carried on by both municipal and voluntary health agencies. The study deals with the problems of infant care, preschool and school hygiene, the work of baby health stations, maternity clinics, day nurseries, camps, hospitals for contagious diseases, and other agencies.

Another significant piece of work done by the Committee in 1923 was the preparation, in response to an inquiry from the Committee on Nursing of the Buffalo Academy of Medicine, of a report emphasizing the following points as regards training of nurses: 1, that the course of training be shortened to cover not more than two years; 2, that the curriculum be revised and more stress laid upon practical experience; 3, that the first year of training be planned so that nurses unable to continue training for

causes other than moral or mental deficiency be allowed to qualify as nurse attendants and as such be eligible for license examinations; 4, that graduate nurse attendants be permitted to work in hospitals; 5, that in planning revisions of the curriculum, the advice and guidance of the medical profession be sought.

The Committee voted to offer its services and assistance in the carrying out of the Milbank Memorial Fund health demonstration to be given in Manhattan in the Bellevue-Yorkville District, comprising an area bounded by East Fourteenth Street, Sixth Avenue, East Sixty-fourth Street and East River. A special committee was appointed to study the causes of the present increasing puerperal mortality rate in New York City and to advise action to be taken by the State. Representatives of the Public Health Committee were invited by Governor Smith to a conference in Albany on outstanding health needs of the State such as health centres for rural communities, drug addiction, and the medical practice act. Advice and suggestions were given along these lines.

Other recommendations were that in all hospitals a Wassermann test be made in every obstetrical case, preferably before admission to hospital; that a coordinating body be organized in New York for formulating medical and administrative standards, particularly in the case of institutions for convalescent care, so that a proper adjustment between supply and demand be brought about; uniform recording of hospital information; and the extension of proper clinic facilities for maladjusted children and the establishment of preventoria for mental and nervous conditions. Special studies completed and now being conducted are of pollution of city air, the medical significance of occupational therapy, Coué-ism, "religious healing," and the desirability of nurse anesthetists.

Legislation affected by the committee's decisions included their advice against changing the present law requiring that children factory workers receive a certain number of hours of instruction during the day, not in the evening after a full working day; the drafting of a bill providing for a board of control to assume the responsibility for meeting the demands of the anatomical departments of the schools of New York State, and to facilitate the administration of the proposed autopsy law, which will enable the hospitals to perform an autopsy on every case if no objection be registered against it by the next of kin within forty-eight hours after notification of death, opposition to the bill introduced at the last session of the New York Legislature giving to employees on the Civil Service list the right to court review under writ of certiorari in case of dismissal, on the grounds that it would be difficult for a health officer or administrator of a hospital to maintain discipline if he were not able to dismiss inefficient employees without so many legal technicalities.

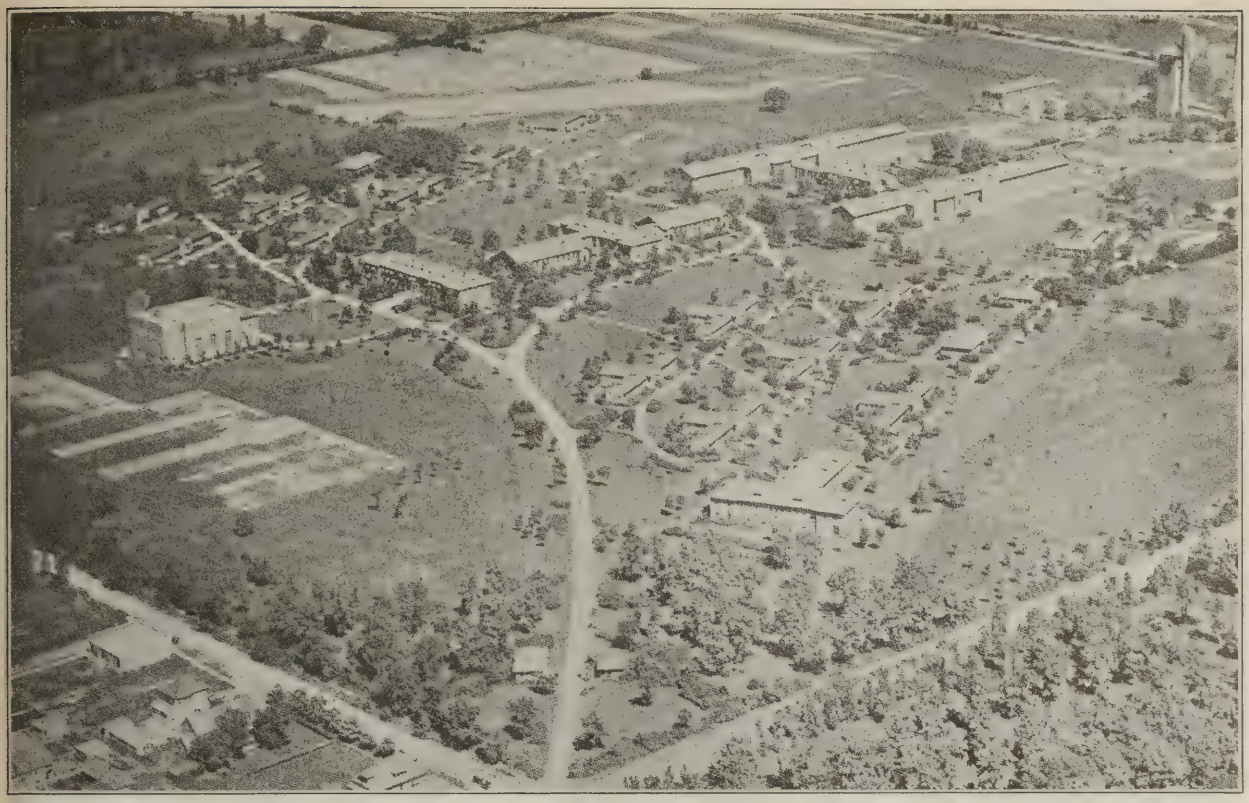
GROUP DIPHTHERIA IMMUNIZATION

There is a growing feeling among public health workers that the Schick test should be abandoned in the immunization of large groups of children. In fact, there are those who believe that it is a useless procedure both in private and public health practice. Kellogg, who has had a wide experience with the toxin-antitoxin immunization procedure in his capacity as director of the Bureau of Communicable Diseases of the California State Board of Health, believes that the Schick test is subject to errors in application which more than offset its informative value.

He points out, in a recent article in the *American Journal of Public Health,* that the causes of errors in the application of a Schick test are due to faulty techic of injection and possible variation of skin reactivity in different areas of the body, that there are many errors in the interpretation of pseudo-reactions, that errors occur from deteriorated toxin, and that lack of experience in the use of the test multiplies all possible sources of error. He has evolved an intracutaneous guineapig test which is convenient and accurate and may be used when it is especially desired to obtain accurate knowledge of the immunization status. Except in such cases he believes that the Schick test is of academic interest only.

His views coincide with those of a considerable number of public health practitioners. False negative readings result in the failure to protect nonimmune children by toxin-antitoxin immunization. Practical tests have shown that in certain age groups practically all children are nonimmune, and since the public health control of diphtheria in the present state of our knowledge depends upon the wholesale artificial immunization of all children, it is believed that, as a practical measure, it is better to immunize all children without reference to their Schick test than to leave even a few unprotected by reason of errors in technic in the application of the Schick reaction.

This is of special interest to the physician in private practice. The general public is learning a good deal about diphtheria immunization and the family physician should be able to give advice and to produce immunization by the toxin-antitoxin procedure. It is certainly true that in those localities where this has been generally done, diphtheria epidemics have ceased to occur. Certainly it is wiser to apply a single operation and do it well than to subject the child to two with a considerable possibility of error.



AIRPLANE VIEW

The Chicago Municipal Tuberculosis Sanitarium

JOSEPHINE COLEGROVE
New York

In spite of advantages in climate and altitude in certain sections of the country, the majority of tuberculosis patients must be cared for in and also by the city where they happen to live. An example of thoughtful and efficient provision for such care can be found in the Chicago Municipal Tuberculosis Sanitarium.

The first tuberculosis clinic in Chicago was the West Side Dispensary of the Jewish Aid Society, founded in 1900 by Dr. Theodore B. Sachs, who is more than any other man responsible for the building of the Municipal Sanitarium. In 1907 the Chicago Tuberculosis Institute was started, with Dr. Henry Favill as president. Its purpose was to give dispensary and nursing service, and the first dispensary was located in a settlement known as Olivet House.

The Glackin Tuberculosis Sanitarium Act was passed by the General Assembly in 1908, giving a city or village the right to determine by direct vote of the people whether or not it would assess taxes for tuberculosis work. In Chicago the vote was taken in 1909 and the majority in favor of such taxation was over one hundred and twenty-eight thousand. The first tax produced $477,000, and the road was open.

For many years Dr. Sachs had dreamed of the ideal tuberculosis sanitarium, and for the two years following the passage of the act he worked daily on the detailed plans. One hundred and sixty acres in the northwest section of Chicago were bought, and the work started and carried on through the vicissitudes of Chicago political life. These led to a suit against the city by contractors who felt they had failed to receive their share of the largess of municipal building. The result was the death of Dr. Sachs, by his own hand—his last note read, "Some day Chicago will know that Theodore B. Sachs loved her."

The sanitarium has a capacity for nine hundred and forty-two patients, about two hundred of whom are children. There is a waiting list of five hundred. Incipient and advanced cases are accepted. Admission is made only through the dispensaries.

From the illustration may be seen the general arrangement of the buildings; the general infirmaries, two groups of open air cottages for ambulent patients, the laboratory, the theatre, the nurses' home, the administration building, and the necessary farm buildings. Building construction is of brick and concrete. The most recent addition is a shelter house for visitors and for visiting children who are not allowed in the sanitarium. Skillful landscape gardening has made the grounds exceptionally attractive and noninstitutional in appearance.

An integral part of the work is the functioning of eight tuberculosis dispensaries, located in crowded sections of the city. Each has a dental clinic, and two orthopedic clinics are conducted. Nursing service is provided for cases receiving home care, including private cases after the dispensary physician has visited the home.

The organization chart of the sanitarium shows a board of directors of three, to whom the general superintendent, Mr. John F. Berry, is responsible. The superintendent of the sanitarium, Mr. Charles A. Reading, and the superintendent of the dispensaries, Dr. Clarence L. Wheaton, are responsible to him. Dr. Peter S. Winner is medical superintendent of the sanitarium.

The biennial report of the sanitarium for the two years ending in 1924 showed approximately sixteen per cent. more admissions of cases of far advanced tuberculosis, with a corresponding decrease in the proportion of incipient cases. In the year 1924 the total number of patients treated was 2,833; these patients remained an average of 29.9 weeks. An average of half the cases admitted are discharged as arrested, quiescent, or improved. Discharged patients are instructed to report either to their private physicians or to the dispensary. Dispensary reports showed a total of 33,384 patients under supervision during the year, of whom 21,481 received treatment. New dispensary patients numbered 4,780. For the city as a whole, over 22,000 diagnosed cases of tuberculosis were recorded, of whom 2,000 were open cases.

The health department enforces a rule that no child under sixteen years of age shall be present in the home of a positive sputum case of tuberculosis. Either the ill person must leave the home, or the child must be removed. The municipal code provides for forcible hospitalization of the patient when this is found necessary. All cases of tuberculosis are reportable, and assigned to the proper dispensary district. Private physicians" cases are recorded as such, but these are visited by one of the nurses, the premises inspected, and an investigation made of whether the patient is carrying out instructions. If the patient has stopped the services of the private physician, he automatically comes under the care of the dispensary.

The research laboratory of the sanitarium is under the direction of Dr. Henry C. Sweany. A finely equipped three story building was finished in 1914. The work is divided into the two natural groups of routine and research, for which an annual appropriation of about fifty thousand dollars is made. The personnel consists of the director, assistant director, physiologist, chief chemist and assistants, serologist and bacteriologist and assistants, tuberculosis research operator, librarian, curator, pathological technician, and patient assistants of various degrees of skill. New methods in routine work have been adopted wherever they have been found practical. Routine blood counts are made on all patients. Vital capacity and blood gas apparatus have been installed. Complete bacteriological slides are done on autopsy material.

OPEN AIR COTTAGE

The general aim of the research work has been to gain a better understanding of tuberculosis and related conditions, to develop the means of making an early diagnosis, and to produce if possible a therapeutic agent. Papers by members of the staff are published from time to time in medical journals. An elaborate monthly bulletin for the lay public is also published.

In a disease such as tuberculosis, the food of the patient is an important part of his treatment. No effort is made to economize on food other than to avoid waste and careless buying. Fresh eggs are served the year around, and cream instead of milk is used for cereals and coffee. Sanitary milk urns are installed easily accessible to all patients, who are

allowed all the milk they care to drink. A farm of some seventy acres and six greenhouses provide the greater proportion of the vegetables used. A bakeshop furnishes over four hundred loaves of bread daily, besides rolls and pastry. Special menus are prepared for patients suffering from diabetes, nephritis, or stomach disorders. All dishes and silver are sterilized by live steam.

The sanitarium assigns fifty physicians for tuberculosis work in the public schools, and the same number of nurses. Cases of suspected tuberculosis are sent to one of the municipal dispensaries for a more thorough examination. The child may then be assigned either to one of the open air rooms at school or to the children's section of the sanitarium for observation and treatment.

The first of the open air school rooms was established in 1909 by the Chicago Tuberculosis Institute and the Board of Education; funds for extending the work to all the schools of the city were given by the Elizabeth McCormick Memorial Fund. Ordinary classrooms are used, ventilated by open windows. Cot beds for an hour's rest daily, and work to all the schools of the city were furnished for each child. A noonday lunch, which must be eaten at the school, costs the child five cents. Nearly two thousand children are cared for. Anemic and undernourished children are received as well as those who have been in contact with cases of tuberculosis or who show signs of glandular involvement. Active cases and subnormal children are not admitted. Careful records are kept, and the child is returned to the regular classes when improved.

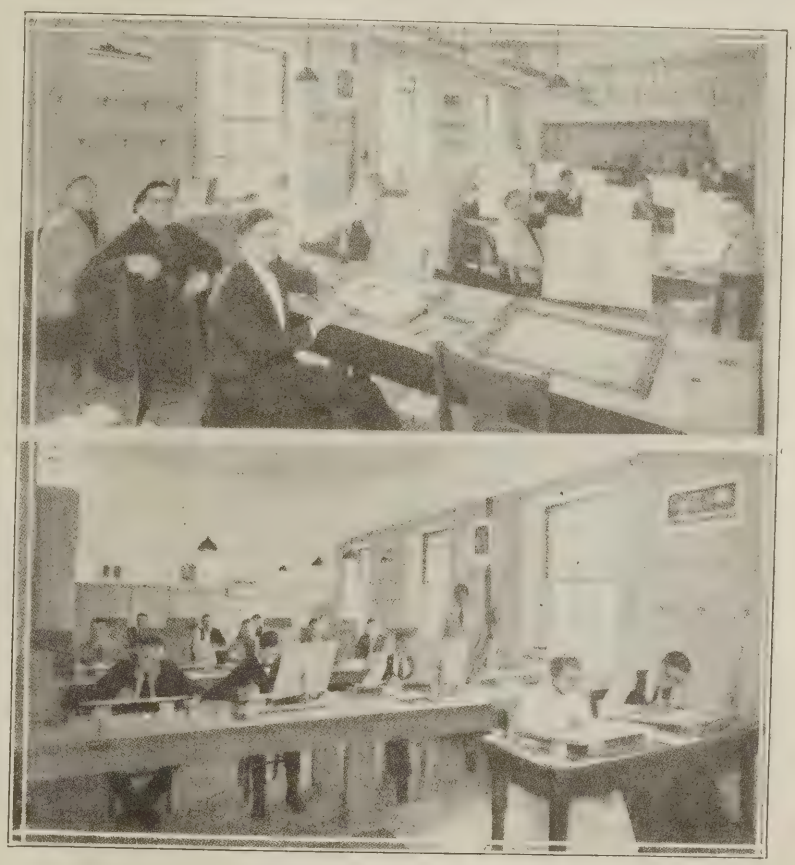
Undernourished children and those predisposed to the disease are cared for during the summer vacation in a tent colony at the sanitarium.

One of the interesting features of the sanitarium is its educational department. Kindergarten, elementary and high school grades, and vocational training are maintained by the Chicago Board of Education—all conducted as open air classes. The work in the elementary grades is the same as that in other city schools. In the high school English, civics, Spanish, science, algebra, geometry, and commercial subjects are taught.

The vocational division not only furnishes a means of seemingly shortening the tedious hours of illness; it is also a direct aid in the future rehabilitation of the patient. Training is given in occupations which will not be detrimental to the health, in the event that some change must be made; and impetus is provided for the utilization of special talents and aptitudes. Classes are held in dressmaking, commercial art, telegraphy, typewriting, barbering, beauty culture, bobbling, carpentry, pharmacy and laboratory work. There has been an enrollment of over twenty in the commercial art classes, and several of the students in being discharged from the sanitarium have been able to continue the work professionally. Training in laboratory work is sufficiently thorough that pupils have been able to take positions as clinical laboratory technicians and bacteriologists.

A beautifully designed theatre faces the administration building. Plays and pageants are produced by the children, and vaudeville and moving picture shows are presented for the benefit of the ambulent patients. Radio sets and reading material are furnished for bed patients. An open air band plays during the summer, and outdoor sports, under proper supervision, are encouraged. The Chicago Public Library has a branch at the sanitarium, and nearly a thousand books a month are circulated. Catholic and Protestant services are held on Sunday.

Social service assistance is provided so far as possible for both sanitarium and dispensary patients. Clothing is supplied by the Service League, an organization of club women in the city; over a thousand patients yearly are helped in this way.



COMMERCIAL ART CLASSES

One of the activities of the sanitarium is the fitting up of outdoor sleeping porches for patients at their homes. Accurate measurements are taken and curtains are carefully fitted to protect the patient in bad weather; blankets are provided. About seventy-five new porches are arranged each year; there are now some four hundred in the city.

From this sketch of the Chicago Municipal Tuberculosis Sanitarium it will be seen that the law has granted it unusual scope for its activities, and that this opportunity is being utilized with skill and devotion.

News Items.

Harvey Society Lecture.—Dr. Knud Faber, professor of medicine of the University of Copenhagen, will deliver the sixth Harvey Society Lecture at the New York Academy of Medicine, Saturday evening, March 13, 1926, at eight-thirty. His subject will be Historical Lines of Therapy.

Medical Mission.—A medical clinic will be established in Cheng Mai, Siam, by Dr. Harry M. McClanahan, of Omaha, in memory of his wife. Dr. McClanahan has recently sailed for that country.

Motion Pictures for Leper Colony.—About two hundred reels of film have been collected by the Motion Picture Producers and Distributors of America, which have been shipped for use at the Palo Seco Leper Colony, near Balboa, Canal Zone.

Dunham Lectures.—Four lectures under the Edward K. Dunham Lectureship for the Promotion of Medical Sciences have been given at Harvard University by Dr. Ross G. Harrison, of Yale. His subject was Recent Advances in Experimental Embryology.

William Beaumont Memorial Fund.—This fund has been presented to the University of Illinois Medical School by Dr. Frank Smithies, of Chicago, to encourage research in the functioning of the digestive mechanism. The first annual reward will be made in 1927.

Smallpox in England.—Nearly three times the number of cases of smallpox have been reported in England for the period from December 12th to January 9th—a total of 960 cases. The cases are mainly in the northeastern part of the country, and appear to be of a mild type.

Gift to Phipps Institute.—Mr. and Mrs. Henry Phipps, of New York, have offered $500,000 to Phipps Institute of the University of Pennsylvania on the condition that the university raise an equal amount. This institute, for the study and prevention of tuberculosis, was founded by Mr. Phipps in 1908, with a gift of $1,300,000, and later gifts aggregated $2,000,000.

Convalescent Home.—A new convalescent pavilion for crippled children has been opened at Camp Hillcrest, Fayetteville, Onondaga County, New York, with accommodations for fourteen boys and girls. This is the gift of the Syracuse Rotary Club and other interested organizations. The cost for the care of the children is met either by the parents or by charitable agencies.

Hospital News.—The Brooklyn Jewish Hospital has completed raising a fund of $1,500,000 which insures the building of a new wing and other additions.

The hospital for students of the University of Illinois, at Urbana, donated by Senator William B. McKinley, of Champaign, has recently been dedicated.

The City Hospital of Indianapolis has laid the cornerstone for a new $385,000 surgical unit.

A mental hygiene clinic has been established at Lebanon Hospital, New York.

Graduate Study.—Courses in oral surgery, anesthesia, exodontia, and oral diagnosis have been arranged by the Joint Committee on Graduate Education of the Long Island College Hospital Medical College and the Medical Society of the County of Kings. Dr. Bertram B. Machat and Dr. Mendel Nevin and their staff will conduct the classes at Greenpoint Hospital, Brooklyn, beginning April 5th.

Personal.—Dr. I. Arthur Stoloff has been appointed associate visiting consultant in surgery at the New York City Children's Hospital, Randall's Island; he has also recently been promoted to assistant professor of minor surgery at the New York Homeopathic Medical College and Flower Hospital, and assistant attending surgeon to the Flower Hospital.

Dr. John Oberwager, of the health department of New York City, has been advanced to the office of general medical expert, to deal with problems concerning the various branches of the medical service of the department.

Dr. Harry D. Orr, of Chicago, has been appointed surgeon general of the Illinois National Guard, succeeding the late Dr. George C. Amerson.

Dr. J. Coleman Scal has received an appointment as assistant visiting otolaryngologist to Gouverneur Hospital.

Dr. J. J. Golub has been appointed assistant director of Mount Sinai Hospital, New York; he was formerly medical director of Beth Moses Hospital of Brooklyn.

Dr. Maxwell Maltz, of New York, will deliver a series of lectures on plastic surgery in Berlin and several other European cities.

Dr. Walter C. Alvarez, of the University of California Medical School, has accepted a position at the Mayo Clinic, Rochester, Minnesota.

Dr. Rudolph Kramer, of New York, has been made foreign corresponding member of the Society of Laryngologists of the Hospitals of Paris.

Dr. Harry Plotz, of the Pasteur Institute, France, formerly a resident of New York, has been made chevalier of the Legion of Honor.

Dr. Carl Landsteiner, of the Rockefeller Institute, has been elected a foreign member of the Swedish Medical Association.

Dr. Charles Philip Miller, Jr., of the Rockefeller Institute, has accepted an appointment as assistant professor of medicine at the University of Chicago Medical School.

Dr. W. C. Noble, of the New York State Health Department, has resigned to devote his time to a professorship in the University and Bellevue Medical College.

Dr. George L. Brodhead, of New York, has been appointed director of the obstetrical service of the Knickerbocker Hospital.

Dr. Alec Nicol Thomson, of New York, has been appointed editor of the *Long Island Medical Journal*.

Dr. Bowman C. Crowell, of Jefferson Medical College, Philadelphia, has been appointed associate director of the American College of Surgeons.

Dr. Louis M. Warfield, of Milwaukee, has been appointed clinical director of the Milwaukee County Dispensary.

Society News and Notes.

The *Ligue nationale française contre le péril vénérien* organized a conference on congenital syphilis between October 5th and 7th, 1925, the object having been to dispel the ignorance still existing about the nature and treatment of venereal diseases. All the leading French dermatologists participated in this congress, and the pediatrists and obstetricians as well. In addition there were more than fifty practitioners from other countries who took part in the discussions or presented papers. It was unanimously agreed as to the necessity of establishing the bases of a common doctrine on which it will be possible to build up social hygiene organizations for combating the principal evils which menace humanity. Prof. Jeanselme of the Paris Faculty of Medicine presided over the conference.

* * *

The Playground and Recreation Association of America has announced a national contest for playground beautification. Three prizes of Five hundred Dollars each are offered to municipal and other non-commercial playgrounds making the best plans and achieving the greatest progress during the period of the contest, which closes on November 1, 1926. In addition to the above mentioned prizes, the Harmon Foundation has announced that it will give thirty-three awards for progress in attractiveness. These awards will be made primarily on the basis of photographs and statements submitted, but inspection trips have also been provided for, and considerations of general appropriateness of the work done will influence final decisions.

* * *

The German Red Cross has recently produced a popular film on first aid in accidents. It is 1,500 meters long and takes fifty-five minutes to run. The film shows how to treat cuts, scratches, burns, fractures and sprains, and those apparently drowned or suffering from exposure. It is planned to be shown not only in public moving picture theaters, but also to illustrate lectures for factory workers, policemen, members of ambulance corps, nurses, and schools and colleges. Red Cross societies of other countries may use this film, either through purchase of copies or by applying for the rights of presentation from the German Red Cross.

At the convention in Indianapolis last October of representatives from children's hospitals and other child caring institutions throughout the country, a permanent Association of Children's Hospitals was organized, with the object that in future hospital meetings the clinical phases of institutional problems will not be submerged in administrative details. The new organization will work in close cooperation with the American Hospital Association. The next meeting will take place in Philadelphia in conjunction with the larger hospital group. The sessions will be arranged in time schedules and scope to serve everyone who may be interested to attend, and definite plans are under way to collaborate with the pediatrics group of Philadelphia to present clinics and conferences of value to hospital executives in particular and to the cause of children's medical service in general.—*Nation's Health.*

* * *

An informal preliminary meeting was held on the evening of February 12th at the home of Dr. S. Jaques Maliniak, 258 Riverside Drive, New York, to discuss plans for the organization of an International Medical Association of New York. No definite plans were made for membership, finances, etc., but it was suggested that each national organization be requested to delegate a certain number of men as representatives in forming the International Association's active membership of executive committee, with the associations as a whole constituting members at large. The objects of the new association are to be: 1, Promotion of medical science through establishing contacts between prominent medical men of foreign countries and the medical profession of New York; 2, Scientific information in regard to medical postgraduate education abroad for the benefit of Americans going to Europe and in New York for the benefit of medical men from other countries; 3, To promote the exchange of lectures and the initiation of courses of study for well known medical men abroad and in New York; 4, To promote medical contacts between the foreign medical societies of New York by arranging medical lectures and courses. Those present besides Dr. Maliniak were Dr. Samuel J. Kopetzky, Dr. Lucien Achard, Dr. Manuel Uribe Troncoso, Dr. Pol. N. Coryllos, Dr. Peter F. Amoroso, Dr. Sirgius M. Inger-man, and Dr. J. Antonio Lopez.

* * *

An association called the Public Baths Association of Sweden has recently been formed with the object of encouraging the establishment of public baths. The association has drawn up descriptive plans of various types of cheap public baths, including exact specifications and designs. At the same time a congress met in Sweden to discuss this subject and lectures were given on different types of baths.

The Committee on Education for 1926 of the New York Academy of Medicine consists of the following members: Dr. James F. McKernon, Chairman; *Medicine:* Dr. Emanuel Libman, Dr. Arthur F. Chace, Dr. Nellis Foster, Dr. Harlow Brooks, Dr. F. B. Cross, Dr. Herbert S. Carter; *Surgery*: Dr. John E. Jennings, Dr. Charles A. Elsberg, Dr. John Douglas, Dr. John J. Moorhead, Dr. Frederick T. Van Beuren, Jr.; *Neuropsychiatry:* Dr. Louis Casamajor, Dr. Edwin J. Zabriskie; *Obstetrics and Gynecology:* Dr. John O. Polak, Dr. George Gray Ward; *Ophthalmology:* Dr. John M. Wheeler, Dr. Arnold Knapp; *Otolaryngology:* Dr. James F. McKernon, Dr. Samuel J. Kopetzky, Dr. J. R. Page, Dr. Isidore Friesner; *Pediatrics:* Dr. R. H. Dennett; *Urology:* Dr. Joseph F. McCarthy, Dr. H. M. Morton; *Orthopedic Surgery:* Dr. Charlton Wallace, Dr. Arthur Krida; *Dermatology and Syphilis:* Dr. Howard Fix, Dr. Hans Jorgen Schwartz; *Roentgenology:* Dr. Joseph M. Steiner, Dr. Leopold Jaches; *Public Health:* Dr. Haven Emerson.

* * *

One of the results of the Child Study Conference held in New York City in October was the organization of a Council of Parent Education composed of fifteen members. The first objective of this council will be the finding and defining of the field of parent education.

* * *

The Association of Life Insurance Presidents has already issued its reports of the proceedings of its nineteenth annual meeting held at the Hotel Astor, New York City, December 3rd-4th, 1925.

* * *

The Gorgas Memorial Institute of Tropical and Preventive Medicine has issued an outline of its recent annual meeting, including a statement of its program for 1926. This will include an intensive campaign through the papers, magazines, radio, moving pictures, clubs, and other agencies, to promote an interest in better personal health. Every citizen in the United States will be urged to set aside one day during the year, preferably his birthday, to go to his personal doctor for a health examination. A national mosquito campaign will be conducted in which the public will be urged to cooperate with health agencies in the eradication of these insects. Arrangements are being made to begin a tropical research program, which will be conducted in laboratories which have been tendered to the Institute pending the completion of its own building. Cooperation between the public and scientific medicine will be encouraged, and a public opinion receptive to proper health instruction developed. Organization of State Governing Committees will be steadily extended and every effort put forth to complete the membership quotas as soon as possible. Present members are asked to help in this by interesting their associates and other representative medical and lay men and women in the Memorial and urging them to enroll in the Committees.

* * *

The Institute of International Education has announced that Dr. Alfred Adler of Vienna is expected to visit the United States for an extended lecture tour in the coming Autumn.

* * *

Officers of the New York Academy of Medicine for 1926 are: Dr. Samuel A. Brown, president; Dr. Herbert S. Carter, Dr. Frederick T. Van Beuren, Jr., and Dr. Charles A. Elsberg, vice-presidents; Dr. D. Bryson Delavan, corresponding secretary; Dr. Seth M. Milliken, treasurer; Dr. John J. Moorhead, chairman of the Committee on Admission; Dr. Frank J. Blodgett, chairman of the Committee on the Library; Dr. Linsly R. Williams, director; Dr. Frederick P. Reynolds, assistant secretary; Dr. Charles M. Williams, historical secretary; Dr. Archibald Malloch, librarian.

Book Reviews

TUMORS

The Pathology of Tumors. By E. H. Kettle, M.D., B.S. Lond., Professor of Pathology and Bacteriology, Welsh National School of Medicine, Cardiff. Second Edition with One Hundred and Fifty-nine Illustrations. New York: Paul B. Hoeber, Inc., 1925. Pp. viii-285.

In this edition the same purpose as in the previous one of providing a manual for students, which should contain the generally accepted teaching on the pathology of tumors without the mass of detail proper in a more ambitious work of reference, has been accomplished and done very well.

The first part of the book deals with the general biology of tumors, including the definition, structure, growth, innocence and malignancy, multiplicity, retrograde changes, dissemination, etiology, experimental study and treatment. The chapter on experimental study is up to the minute, including, as it does, the recent work of Gye, which has attracted such universal attention.

In Part II, the general pathology of tumors, the latter are classified as innocent connective tissue tumors, sarcomata, innocent epithelial tumors, carcinomata, endotheliomata, hypernephromata, melanomata, and teratomata.

Part III is concerned with the special pathology of tumors, dealing with the tumors as they occur in the different systems and organs of the body.

This book is ideally adapted to the needs of the medical student, whom it gives a very clear and up to date idea of what is known of tumor pathology. Numerous illustrations adorn the book.

EYESIGHT

Eyesight Conservation Survey. Compiled by Joshua Ayre Hannum, M.E. Edited by Guy A. Henry. (Bulletin No. 7.) New York: Eyesight Conservation Council of America, 1925. Pp. 219.

The scope of this report is indicated by the eight subdivisions of the subject of eyesight conservation into which the discussion is divided. These are Eye Hygiene, Eye Defects, Eye Diseases, Eyesight and Education, Eyesight and Occupation, Eye Protection, Illumination, and The Eyesight of Noted Persons. An excellent bibliography completes the volume. It is evident that the report summarizes the results of an extensive survey of the whole subject of eyesight conservation. The style of presentation is nontechnical, and for the benefit of the lay reader a section of definitions of terms is inserted at the beginning of the book. Among the activities productive of the material on which this report is based were studies of the statutory provisions of all states relating to vision tests of school children, and surveys of the public school systems of 250 of the largest cities in the United States, of 300 normal schools and teachers' colleges, of 750 colleges and universities, and of 750 industrial and commercial establishments. The statistics presented of defective vision among school children and industrial workers are a challenge to the social system. Simple acuity tests, for instance, revealed that 25 per cent. of the children in the public schools of the country have manifest defects of vision and symptoms of eye strain. Much more serious conditions were found in workshops and factories. The final chapter on Eyesight of Noted Persons includes some curious data probably never before presented. Among those persons who suffered from eye ailments were Francis Parkman, Tschaikowsky, George Eliot, Wordsworth, Theodore Roosevelt, Goethe, Swift, H. G. Wells, Balzac, and Nietzsche. Whittier was color blind and Taine was cross eyed. Relentless use of the eyes is said to have hastened the death of Balzac.

HELIOTHERAPY

Die Lichtbehandlung (Heliotherapie) in den deutschen Lungenheilanstalten. By Sanitätsrat Dr. Georg Liebe; Leipzig: Curt Kabitsch, 1926.

This is a posthumous publication by Sanitätsrat Dr. Georg Liebe on heliotherapy in German sanatoria, preceded by a tribute to Liebe by Prof. Dr. Martin Kirchner and supplemented by articles by Bochalli and Scheffer. The work itself is revised by Dr. Hans H. Meiners. Prior to writing the work, Liebe had addressed letters of inquiry to the various sanatorium directors and on the basis of the replies and his own experience he laid down the modus operandi for the treatment of tuberculosis by the air bath, the sun bath, quartz light, ultraviolet light, and deep röntgen rays. In the application of natural as well as artificial heliotherapy, nearly all reports indicated that they followed the well known principle laid down by Rollier with the necessary precautions which pulmonary tuberculosis demands. Many applied the air bath, fewer applied sun baths, but nearly all complained of lack of facilities to give the air bath outdoors, not being able to secure a large enough space or to give the necessary privacy.

Dr. Bochalli, director of the sanatorium Moltkefels, sums up the reported results by saying that heliotherapy as carried out in high altitudes for joint tuberculosis, is all important but that, while subjective improvement could be reported in many cases of pulmonary tuberculosis, not in a single instance could he come to the conclusion that any decided improvement in the condition of the lung could be ascribed to the influence of sunlight. As the result of his own experience, he says artificial light, such as quartz light, etc., seems to have a beneficial action on the cutaneous and nervous system, producing a general well being, but these results were the same as those obtained in the otherwise routine treatment at sanatoria.

Dr. Scheffer reports the success obtained with the aid of heliotherapy in chronic middle ear affections (suppurative otitis media). Of five cases reported, in four the treatment was an absolute success.

As a whole, the booklet of forty pages is well worth a careful perusal by all physicians interested in the treatment of tuberculosis, but particularly by those who are so situated as to be able to resort to the treatment of their patients by air, sunlight, and the newer devices, such as quartz lamps, deep röntgen apparatus, etc.

CHEMISTRY FOR MEDICAL STUDENTS

Anleitung zum Chemischen Praktikum für Mediziner, Theoretisches und Praktisches. von Dr. phil. Ernst Pfau. Nahrungemittelchemiker und appr. Apothekar, Oberassistent am Chemischen Institut der Tierärztlichen Hochschule Hannover. Leipzig: Verlag Von Johann Ambrosiaus Barth, 1926.

This is a very useful, highly condensed, laboratory guide for medical students' courses in medicine. Into the compass of ninety-six pages a very considerable amount of chemistry has been compressed.

PHYSIOLOGICAL CHEMISTRY

An Intermediate Textbook of Physiological Chemistry with Experiments. C. J. V. Pettibone, Ph.D., Associate Professor of Physiological Chemistry, Medical School, University of Minnesota, Minneapolis. Third Edition. St. Louis: The C. V. Mosby Company, 1925. Pp. 404.

This is a useful short summary of physiological chemistry for the medical student. The major part of the text is descriptive, is well written, and contains all that is needed. The practical exercises are limited to matters of importance, either from the theoretical or diagnostic aspects.

CHEMISTRY

Physiological and Clinical Chemistry. By William A. Pearson, Ph.C., Ph.D., M.D., Professor and Head of the Department of Chemistry, Physiological Chemistry and Toxicology in the Hahnemann Medical College and Hospital of Philadelphia, and Joseph S. Hepburn, A.M., B.S. in Chem., M.S., Ph.D., Associate Professor of Chemistry in the Hahnemann Medical College and Hospital of Philadelphia. Illustrated. Philadelphia and New York: Lea and Febiger, 1925. Pp. 306.

This is a convenient laboratory guide on clinical chemistry, interleaved for student notes. It stands midway between the laboratory guide, which contains nothing but skeleton directions, and the larger textbook on physiological chemistry. The reviewer questions whether it would not have been better to have made the book a little more full and omit the interleaving. The student would have then bought considerably more information, and a ten cent notebook would have furnished him with the necessary records of new material given him by his instructors.

DIABETES

Traitement du Diabète. Par Pedro Escudero, Grande Librairie Médicale A. Maloine. Paris: Norbert Maloine, 1925.

This French edition is not merely a repetition of the original issue in Spanish. The author has added many details, amplified the table of values of dietetic units, and appended a chapter on the therapeutic use of insulin, with a study of the problems arising in its administration, whether as to dangers, or as to results. In successive chapters we review the mechanism, causes, symptoms, prognosis and treatment of diabetes, and, particularly, its hygiene. Normal alimentary rationing and the antidiabetic regimen are then considered at length. Acidosis has a separate chapter of special value. Escuderos is convinced that regime as it always has been will always continue to be the basis dietetic of the treatment of diabetes. Insulin, he asserts, has neither modified nor simplified this treatment. It has merely rendered really efficacious.

NURSES' TRAINING

Elementary Anatomy and Physiology for Nurses, including chapters on psychology, biology, comparative anatomy and embryology. By H. Clifford Barclay, M.D. Third Edition. Illustrated. New York: William Wood & Company, 1925. Pp. 411.

The principal changes which this third edition of Dr. Barclay's book shows are a considerable enlargement, the addition of a number of plates and illustrations, a chapter on psychology, giving a brief discussion of its relation to the main theme in its individual and crowd aspects, and the addition of diet tables. These last have been added, the author states, because "the details that investigating physicians will bother with today, will become the ordinary duty of the sister and matron to know tomorrow. The probationer of today when qualified will probably be asked to arrange her diets in calories by the time she has reached the rank of a sister. I am looking ahead." Reproductions of a number of x-ray photographs have been added in this edition to the original plates.

In this as in the former editions the aim of the author is to present his discussion of human anatomy and physiology so as always to emphazise the fact that they are but aspects of that larger and more inclusive subject, biology. The book is intended for hospital probationers, but the style is so simple and untechnical that it could readily be adapted for use in high schools and colleges. The plates and other illustrations are excellent, and a good index completes the volume.

MEDICAL ESSAYS

More Things that Matter. By Lord Riddell. London: Hodder and Stoughton, Ltd., 1925.

The essays and sketches in this book, written by Lord Riddell were published originally in *John o' London's Weekly* and were republished in book form in response to requests from many readers. From several points of view the author deserves the attention of medical readers. First, because he has done a great deal for the hospitals. He is chairman of the Royal Free Hospital, London, where the students of the London School of Medicine for Women receive their clinical training, and it is largely owing to his efforts that the hospital, to use an Irishism, has been put on its feet. Moreover, in the book are two or three essays which will especially appeal to medical men. One of these entitled "Mind and Body," deals with the subject of the inter-relation of body and mind and how by the correction of physical conditions as septic teeth or tonsils or intestinal toxemia, sometimes mental disorders can be improved or even cured.

Another essay discusses the drink question, Drink: Poison or Panacea. Although Lord Riddell is, and has been always a rigid teetotaller, he is not hidebound in his outlook or prejudiced in his views on the drink question. He knows that drink in excess is harmful and he also knows that it is not essential to health in any circumstance but, at the same time he is able to perceive that it may possess redeeming features. He is somewhat inclined to agree with the conclusions of Professor Starling, who in *The Action of Alcohol on Man* (Longmans) edited a kind of scientific apologia for alcohol not long ago.

In yet another essay, under the title The New Slavery, prohibition is commented on and the arguments for and against this extremely intriguing not to say embarrassing matter are marshalled or rather referred to in good humor and impartially. He points out that prohibition is a great interference with personal liberty and states that the autocratic methods which prevail in America would not be tolerated in Great Britain even if thought to be for the good of the country. The author further points out that in Norway "limited prohibition" which means the forbidding of beer and spirits has proved a dismal failure. He wisely refrains from criticizing conditions in America, which seem very open to criticism. The law here is more honored in its breach than observance, with consequences greatly deplored by sensible citizens throughout the country. The success following restrictive measures in Britain are referred to.

The chapters on the art of public speaking, in which the author is an adept, are excellent, and the sketches of public men are particularly well done. They are for the most part finely drawn word pictures. The distinguishing feature of the book is its common sense, but common sense raised from a monotonous level by brilliant writing and the infusion of wit and humor. The book may be recommended to the medical man both as a source of information and of distraction from the woes and worries of this troublesome world.

Medicoliterary Notes.

Among articles of special interest in the *Nation's Health* for December 15, 1925, are From the Family Doctor to the Medical Center, by Dr. C. C. Burlingame, executive officer of the New York's new Medical Center; Health Problems as Shown by College Medical Examinations, by Dr. J. Howard Beard, of the University of Illinois; and Organized Advertising Attacks Medical Frauds, by Holland Hudson, of the Associated Advertising Clubs of the World.

* * *

With a view to showing how the loss of men in the World War has affected the economic life of France, Gaston Cadoux, former president of the Paris Statistical Society, has drawn up tables showing how the 1,363,000 dead men were employed before the war, according to the *New York Times*. The biggest loss was to the land, 669,000 of the men having been farmers and land workers out of a total agricultural male population of 5,500,000. Industry gave the next largest figure with 235,000 out of 2,000,000. In commercial pursuits, 159,000 men fell, out of 1,327,000. The civil service gave 21,000 out of a total of 500,000 and the liberal professions 40,000 out of a total of less than 250,000.

* * *

The first Chinese hospital in San Francisco has recently been opened. It is an outgrowth of the dispensary for the care and treatment of the poor which was opened in 1900 by the Chinese Six Companies. A few years ago the necessity for a hospital became evident, and fifteen different organizations banded together to raise the funds needed to build the present institution.

* * *

The *American Journal of Public Health* for December, 1925, contains reprints of the addresses made and papers read at the fifty-fourth annual meeting of the American Public Health Association at St. Louis last October.

* * *

The noise and clamor of modern city life are producing a race of elephant eared men and women, says Dr. Fritz Pfuffer, a Vienna ear specialist. Women will be hardest hit because they wear their hair over their ears, thus making hearing even more difficult. Dr. Pfuffer bases his prediction upon the measurements of his patients' ears during the past thirty years. The continuous strain on the auditory nerve is the cause of the change, he states.

* * *

The Health Committee of the League of Nations has just issued its report of the proceedings of its fifth session, held October 8-14, 1925. One of the features of the sessions was the report and discussions of the work of the Malaria Commission.

* * *

The "Wellcome" Photographic Exposure Calculator Handbook and Diary for 1926 is a practical little book for those interested in photography. Not only is the photographer told how long to expose a given plate or film, but he is told how long to develop it at certain temperatures, how to finish off his negative, and how to get the best print from it.

* * *

The Hungarian Ministry of Public Welfare has issued an order that all employees of the Hungarian State Railways, including apprentices, and widows and orphans of pensioned employees must be insured. The benefits are free medical and hospital treatment, free drugs and health resorts, sick benefits, medical and obstetrical treatment in childbed, subsidy during the last six weeks of pregnancy, further subsidy for twelve weeks after the birth of the child, and burial subsidy.

* * *

Officials of the London Zoo got the surprise of their lives not long ago. In a tank were several octopuses, one of which mysteriously disappeared. The missing octopus had a body about the size of a baseball and tentacles about eighteen inches long. The remaining octopuses were studied, especially their stomachs, for it is a well known fact that an octopus will eat a friend as well as an enemy. But there was nothing to indicate that the missing one had been eaten. The mystery grew deeper until the lost octopus was discovered one day in the act of returning. He was emerging from a small slit in the aquarium tank three inches long by one third of an inch in width. Reduced to human terms, this would mean that a Times Square traffic officer climbed through the slit in a letter box and, not being happy over what he found inside, climbed out again.—*New York Times.*

* * *

Prof. Stanley Thomas of the department of bacteriology of Lehigh University has contributed an article of unusual interest to *Public Health Reports* for January 8 on Smallpox Vaccination as Carried Out at Lehigh University. Professor Thomas states that he is firmly convinced that education of the public in the desirability of vaccination is of greater value to the public than law enactments. He advocates the universal employment of the method of the U. S. Public Health Service, and believes that with its adoption this means of protection against smallpox will be welcomed rather than dreaded.

* * *

An important article in the *World's Health* for December, 1925, is that of Louis I. Dublin, Ph.D., of the Metropolitan Life Insurance Company on the Excesses of Birth Control. This is a reprint of an address delivered before the Sixth International Neo-Malthusian and Birth Control Conference held in New York City in March of 1925.

* * *

It has been computed by conservative physicians that 40 per cent. of their service is gratuitous, either through voluntary service or through clients' failing to pay the doctor's bill. A cursory survey of the gratuitous service given by physicians through medieval institutions in the Greater City of New York, based upon the number of free hospital days, aggregates $16,000,000 annually, according to a statement recently issued by the National Endowment Fund for the Physicians' Home which is being planned by prominent doctors of the country. This figure by no means indicates the total bill that the city controlled and private hospitals would have to pay if the doctor, like other professional men, demanded and received payment for each and every service performed. It is based upon the returns from but 107 of the 140 odd medical and surgical institutions giving some portion of charity service. Evaluating the physician's service nationally upon the hypothesis that outside New York City but a pro rata service in quantity is given equal to 50 per cent., and assuming that each hospital day's service was paid for at the rate of $3.00 per day, the nation's bill due the doctor would be more than $135,000,000 annually.

Abstracts from Current Literature

SYPHILIS

Clinical Studies on the Kahn Reaction for Syphilis. II. Specificity of Test.—Harther L. Keim and R. L. Kahn (*Journal of Laboratory and Clinical Medicine,* September, 1925) present the results of parallel Kahn and Wassermann tests in 2,500 cases which were nonsyphilitic. The Kahn test was negative in 2,493 cases, giving seven reactions varying from one to three plus. These results indicate a high degree of specificity.

Observations After Ten Years on a Series of Cerebrospinal Syphilitics Treated by Intravenous and Intraspinous Therapy.—George Draper (*American Journal of the Medical Sciences,* January, 1925) published in 1915 a series of cases of cerebrospinal syphilis which had been treated for from six months to two years after the manner of Swift and Ellis. Examination ten years later of the members of this series which could be reached lead him to the following conclusion:

The Swift-Ellis method of treatment undoubtedly is effective in a certain type of case, representing, according to this small but varied series, about thirty-six per cent of all cases of cerebrospinal, or central nervous syphilis.

Successful results of the treatment of cerebrospinal syphilis do not depend alone upon the spirocheticidal effect of salvarsan and mercury, there is undoubtedly some other factor developed in the course of the treatment, which successfully raises the resistance of the individual. When this resistance elevator fails to develop, no amount or intensity of treatment with salvarsan, serum and mercury can check the destructive advance of the disease.

In view of the tendency to recrudescence, all patients who are apparently cured should be instructed to report for physical examination and spinal fluid test every two years and possibly oftener.

Diagnosis of Chronic Late Syphilitic Arthritides.—Hermann Schlesinger (*Wiener klinische Wochenschrift,* February 5, 1925) emphasizes the following points:

The diagnosis is readily made from an admitted infection, from previous remittances of symptoms after antisyphilitic treatment, or from a history of repeated miscarriages in the wife or the evidence of hereditary syphilis in the children. There may be definite gummatous changes in the skin or the mucous membranes, characteristic changes in the bones, gummatous diseases, late syphilids, or specific changes in sensory organs. The Wassermann reaction may be positive. However, the arthritic disease may be of a nonsyphilitic nature in a syphilitic patient. Unfortunately the history and the other findings may be negative.

Physical examination and observation often help in the diagnosis. The condition is frequently refractory to salicylate therapy and other antirheumatic measures. If the various tests with tuberculin and gonococcus vaccines result negatively, syphilis should be given consideration. Gout must also be eliminated.

A peculiar localization of the disease is characteristic, especially in the sternoclavicular joint; the joints of the jaw and the vertebral column may also be involved. Symmetrical lesions of joints, especially of the knee joint, have been known to occur in hereditary syphilis for a long time. Any joint may be involved. The order of frequency of joint involvement is the following: knee, ankle, elbow and the joints of the hand; the hip joint is involved least often. There is no traveling from one joint to another as in acute rheumatic infection, and the frequent recurrences are of a local nature and affect joints previously involved.

The pains are usually severe and generally show nocturnal exacerbations. The pains may last for months, being influenced by neither antirheumatic or antineuralgic remedies, but they respond promptly to specific remedies. Pain on motion is also generally present. The function is usually impaired considerably less than one would expect; fixation of the joint and severe articular muscular atrophy are rare. Circumscribed points of tenderness are usually demonstrable. These points of tenderness usually correspond with circumscribed anatomic changes.

The Wassermann reaction is often negative in the blood serum, but it may be positive in the articular punctate. It is usually more markedly positive in the joint fluid than in the blood serum. The luetin and precipitation reactions may also be negative in the blood serum, but positive in the joint fluid. The blood Wassermann, however, may become positive after antisyphilitic treatment.

The röntgenographic findings are usually not definite. The most important findings are the following: multiple, preferentially circular periostitides in the long tubular bones, the absence of an acute Sudeck bone atrophy, and focal disease of the articular cartilage with hypertrophic changes at the border of the joint space. Thickening of the joint capsule, partial destruction of the ligaments, rarefying osteitides, and possibly circumscribed destructions of bone may be of diagnostic value. Restriction of the involvement to one joint, the neighboring joints remaining intact, is quite characteristic.

The heart and large bloodvessels are strikingly seldom attacked. In these cases the spirochetes seem to have a predilection for the connective tissue and locomotor system.

The pharmacological reaction is of the greatest diagnostic value. This term refers to typical reactions after the administration of specific drugs. A moderate amount of blue ointment is applied to a painful joint. This application results in either an immediate marked remission of the pain or the remission may be preceded by a marked aggravation of the pain. The transient aggravation may be looked upon as a Herxheimer reaction. Specific remedies administered in the form of subcutaneous or intravenous injections of mercury, iodid, arsphenamin, or bismuth produce typical reactions. These may be either of a general nature, focal reactions in markedly changed joints, or in apparently unaffected joints and bones. 1. The general reactions are inconstant; there may be a febrile reaction, sometimes associated with beginning chills or profuse sweating, after a few hours. 2. The focal reactions in the affected joints are usually pronounced. The pains are increased, the articular swelling may increase, the skin over them is reddened, sometimes edematous and feels warm. 3. Focal reactions in apparently unaffected joints do not last long. Most frequently there is tenderness over the sternoclavicular joint, the sternum and the calvarium. The author considers the pharmacological reaction as one of the most constant and important signs of late syphilitic arthritis.

The treatment should be both general and local, including also the measures that are known to affect the joint condition favorably.

DIABETES

Diabetes. Surgical Infections and Insulin.—R. Carrasco-Formiguera (*Lancet,* May 23, 1925) summarizes his personal experience in cases of surgical infection in diabetic patients and of their treatment by insulin as follows:

1. Even in the more severe cases of infection in diabetic patients it is always possible (unless there is not enough time before the patient dies) to attain a normal blood sugar level if insulin be used in large enough doses properly spaced throughout the day.

2. It may be difficult, or even impossible, to keep the blood sugar level absolutely normal all the time through, but it may be kept so most of the time and not far from normal the rest of the time.

3. Such a result may be obtained without any dangerous underfeeding, which must be carefully avoided. In fact, with an adequate combination of diet and insulin such patients may be kept sugar free and at the same time well nourished, much better than would be possible by any other known measures, dietetic or otherwise.

4. In many cases infection in a diabetic patient may follow a favorable course even when there is a certain degree of glycosuria or hyperglycemia, but in other instances it may be very different.

5. So long as given case of infection in a diabetic patient, in which glycosuria or even only hyperglycemia persists, is not doing well, all efforts must be made to render the urine sugar free or even to attain a normal blood sugar level with the help of insulin and avoiding undue underfeeding.

Glycosuria, the Symptom.—Walter R. Campbell (*Lancet,* March 14, 1925) states that resembling, as these cases of symptomatic glycosuria do, the less severe cases of diabetes in many particulars, it is of considerable importance to the patient's future that they should be accurately differentiated from true diabetes mellitus, since their prognosis is good and is not in any way improved by dietary restrictions. However, until sufficient evidence has been accumulated to justify freeing these patients from the diabetic regimen, they should be treated as diabetics.

Certain characteristics are common to this group, which help to separate it from diabetes mellitus. First, they are symptomless apart from glycosuria unless, perchance, they have previously undergone an excessively rigid dietetic regime, resulting in weakness and emaciation; second, they are usually discovered accidentally during routine physical examination; third, the glucose percentage and total excretion of glucose in twenty-four hours is small; fourth, the glucose is unaccompanied by acetone bodies unless there are other causes for their presence, such as pregnancy or starvation; fifth, increased carbohydrate intake does not produce a commensurate increase in the glycosuria; sixth, the respiratory quotients after glucose ingestion rise to values around 1, indicating the normal utilization of carbohydrate; seventh, the condition shows no tendency to progress even under dietary conditions highly unfavorable to the true diabetic. Probably the most significant differentiating point, however, is the fact that in such cases glycosuria can be repeatedly shown to be present while the blood taken at the same time shows a normal sugar content.

It has been shown that diabetes is due preeminently to a failure of the islet tissue of the pancreas to function normally. Carbohydrate metabolism is thereby impaired, hyperglycemia results, and glycosuria occurs when the blood sugar reaches an excessively high level. Treatment for the condition is not to be directed to abolition of the glycosuria, though this is an incident when treatment is successful, but to the provision of adequate rest to the pancreas from overwork, the maintenance of a normal blood sugar level, and, at the same time, provision of sufficient calories to restore to the individual the ability to do physical work.

The necessity of carefully differentiating glucose from other reducing substances in the urine is emphasized, and when glucose is actually present the importance of distinguishing between the accidents and anomalies of carbohydrate metabolism and the disease diabetes mellitus must be appreciated.

Local Insulin Reactions.—R. D. Lawrence (*Lancet,* May 30, 1925) states that besides its general action on blood sugar and carbohydrate metabolism, insulin causes definite local effects and reactions at the site of injection. These reactions vary with the individual, the site of injection, and the brand and batch of insulin used.

The local reactions may be conveniently divided into immediate and delayed. In all cases it is the hypodermic injection of insulin that is described and not the intradermic or intramuscular. Intradermic injections meet with great resistance, cause an obvious pigskin appearance, and much local irritation, swelling and pain, and should always be avoided. Intramuscular injections cause no obvious swelling but a deepseated pain which lasts from twelve to thirty-six hours. Patients should keep their syringes in methylated spirit or absolute alcohol, and never sterilize them by boiling or strong antiseptics.

The immediate local effect of an injection of insulin is stinging at the site of the injection. This is most marked during the first few days of treatment and is rarely troublesome after ten days. The tissues seem to acquire a local tolerance to insulin and stinging is likely to recur when the injections are made in some other part of the body. Local urticarial wheals occasionally appear, often when the injection is partly intradermic. It is anaphylactic in nature.

Delayed local reactions are much more troublesome. They closely resemble vaccine reactions and are more likely to occur in the obese. They may cause much pain and irritation and can be partly alleviated by cooling lotions. They usually disappear after two or three weeks. General anaphylactic reactions have also been reported.

Subcutaneous thickenings and great thoughness of the skin following frequent injections in any one part of the body may be prevented by changing the site of the injection from one arm or thigh to another or to the chest or abdomen every week or ten days. Usually a change of the batch or brand of the insulin is the cause of the trouble.

The pain of the puncture can be minimized by the use of fine and sharp needles, and by inserting the needle as nearly at right angles to the skin as possible. Usually, by moving the point of the needle lightly over the skin it is easy to find a spot which is quite insensitive to the prick and where the injection can be made quite painlessly, because it avoids the nerve endings for pain. The sting of the insulin is usually very slight and it can be made less by pinching somewhat vigorously the skin and underlying tissues into which it is being injected. The best sites for injection are the parts of the body where the skin is loosest and which are not subject to pressure or too much movement in the underlying muscles. The calves are unsuitable because the skin is very tight over them, and the best places for self-administration of insulin are the front and outer aspects of the thighs, the abdomen, and the lower part of the chest. The forearms and outer sides of the upper arms are also available when someone other than the patient is giving the injection.

OBSTETRICS

Effect of Popular Gynecological Procedures on the Future Childbearing of Women.—John Osborn Polak (*Canadian Medical Association Journal,* September, 1924) says that too many women are operated upon, many needlessly. Sterility operations give poor results and often have unfortunate sequelæ. The gynecological patient seldom has a complete diagnosis before operation is advised. When possible operations on childbearing women should be deferred; better obstetrics, better postpartum care and the use of pessaries will keep these women comfortable. Every abdominal operation has its morbidity, is followed by some intrapelvic pathology and a small mortality. Greater care should be used before determinng on Cæsarean section.

Cæsarean Section After Labor Test.—H. M. Armitage (*Surgery, Gynecology and Obstetrics,* October, 1925), asserts that the low operation is indicated when the membranes are ruptured and examinations by the vagina or attempts at delivery have been made.

When the low Cæsarean is decided upon the uterus should be eventrated, the abdominal wall closed, and precautions taken to prevent infection of the peritoneal cavity by "spill," gloves, or instruments. With the uterus eventrated the operation is performed with remarkable ease. Thus its applicability is extended to included the field of the general surgeon by whom most Cæsarean sections are performed.

The slight increase in shock caused by lifting the uterus out of the abdominal cavity is more than compensated for by the effectual protection afforded to the peritoneum.

Placental Transmission. The Aminoacids, Nonprotein Nitrogen, Urea, and Uric Acid in Fetal and Maternal Whole Blood, Plasma, and Corpuscles.—E. D. Plass with the assistance of C. W. Matthew (*Bulletin of the Johns Hopkins Hospital,* June, 1925) analyzed the fetal and maternal whole blood and plasma from twenty normal patients at the term of delivery for aminoacids, total nonprotein nitrogen, urea and uric acid. The aminoacids were found to be uniformly higher in normal fetal whole blood and plasma than in the maternal. The total nonprotein nitrogen was likewise always in higher concentration in the fetal whole blood and plasma. Urea was usually equal in concentrations in the two bloods. Uric acid was usually found in equal concentrations in the two circulations, but, if there is a difference, it is generally higher in the fetal blood.

Value of the Wassermann and Sachs-Georgi Reactions in Obstetrics.—Karl Burger and Ludwig Heiner (*Zentralblatt für Gynäkologie,* March 22, 1924) arrive at the following conclusions:

1. During the puerperium (especially after the first eight days) the Wassermann reaction is more reliable, inasmuch as the Zachs-Georgi reaction frequently gives nonspecific reactions, as was shown by the authors' investigations during pregnancy and six to eight weeks after delivery.
2. Blood from the umbilical veins and retroplacental blood give no reliable results.
3. The duration of the labor and the albuminuria of pregnancy have no effect upon the serological reactions.

The contraindications include an active process in the more healthy lung, intestinal tuberculosis, severe cardiac and renal disease, advanced age, and also very extensive pleuritis adhesions on the better side.

Hemorrhoids in Pregnancy.—C. Rosser (*American Journal of Surgery,* March, 1925) designates the following situations as those suggesting or requiring surgical intervention: The presence at the outset of gestation of hemorrhoids, certain to prove annoying when aggravated by continuation of pregnancy. Complications, such as excessive bleeding, ulceration or gangrene. Thrombosed external piles, where removal of the clot and redundant skin under local anesthesia will correct an otherwise annoying situation. The modern technic for hemorrhoidectomy, embracing local anesthesia, absence of traumatic divulsion of the sphincters to cause bladder disturbance, and the excision and ligation of the piles, permits bowel function in forty-eight hours when necessary and can be performed without fear of interruption of pregnancy.

Uterine Myomata and Pregnancy.—P. B. Bland (*Surgery, Gynecology and Obstetrics,* March, 1925) asserts that the simple presence of a myoma in the uterine wall is no indication for treatment. Even myomata in such a position ostensibly as to act as a barrier to parturition may rise out of the pelvis and permit of fetal exit. Unless the tumor excites acute symptoms, irrespective of its position, it should not be disturbed, but treated along simple expectant lines.

Tumors occupying persistently an obstructive position in the pelvis, provided they are agreeable to the patient, we believe, do not call for treatment until near term, when an elective Cæsarean operation may be performed and the tumor removed either by conservative myomectomy, depending upon the size of the tumor and the wishes of the patient, or a hysteromyomectomy depending again upon the wishes of the patient and the exigencies of the case. With regard to therapy in those cases associated with necrosis and acute symptoms, one can safely say that this will depend upon the extent of the necrotic process and severity of the symptoms.

Management of Occipitoposterior Position.—S. J. Scadron (*Surgery, Gynecology and Obstetrics,* May, 1925) advocates Kjelland forceps for transverse and oblique positions of the head, and for biparietal application. In this opinion they possess the following advantages over the ordinary forceps:

1. They are easy to apply in spite of the position of the head, and the direction of the sagittal sutures; no special experience in technic is required.

2. The position of the head is not altered by the application. This is an important fact, especially when there is slight pelvic contraction, in which case the ordinary forceps displace the head defeating nature's attempt.

3. It is necessary to introduce only two fingers instead of the whole hand as is sometimes necessary when the head is high up. This reduces the chances of infection.

4. The biparietal application does not permit the slipping of forceps. The point of the blades remains on the face near the chin and the blades run parallel with the long axis of the ovoid head and firmly grasp the head. The traction on the face is not only directed against the points but there is an even pressure of the entire instrument. There is no direct pressure over the eye, no pressure on the face, neck or facial nerve as with ordinary forceps.

5. Better rotation is obtained because the forceps can be applied in one position.

6. This application aids the normal mechanism in terminating labor.

7. Less force is required.

TUBERCULOSIS

Articular Surfaces in Tuberculous Arthritis.—D. B. Phemister (*Journal of Bone and Joint Surgery,* October, 1925) in studying the changes in articular surfaces in this disease, finds that in the earlier stages of tuberculous arthritis, in joints with both free and contacted articular surfaces, the articular cartilage is usually destroyed most extensively along its free articular surfaces by granulations which overgrow it from the surrounding synovial membrane. In the regions of contact and pressure of articular surfaces, surface destruction by granulations does not take place and the cartilage is preserved longest. As the disease progresses, subchondral granulations develop which absorb articular cortex and attack the cartilage from beneath. In severe tuberculous arthritis there may be early necrosis and caseation of the overgrowing synovial granulations, so that there is little or no destruction of articular cartilage along its free surfaces. In this event the destruction of articular cartilage is brought about mainly by the subchondral granulations, which do not undergo early necrosis and caseation and do not present the usual histologic picture of tuberculous tissue. The bony involvement along the articular surface may be either primary or secondary. When primary, the dead bone may break down, leaving a cavity, or may persist and form a sequestrum which has articular cortex and in some instances cartilage preserved on it and is denser than the surrounding living bone which subsequently atrophies. Secondary involvement of bone along the articular surfaces may lead either to destruction of the entire articular cortex by superficial caries or to more or less extensive and deep areas of necrosis at the points of greatest pressure in the joint. This deep invasion is often bilateral and is followed by the formation of "kissing sequestra," which may be mistaken for primary foci of osseous infection.

Intestinal Tuberculosis.—A. N. Bessessen, Jr. (*American Journal of Surgery,* September, 1924) finds that early diagnosis is necessary if results are to be expected. Rest is the basis of all methods of treatment. Under proper supervision, in favorable cases, either medical or surgical treatment will give good results. The pulmonary condition and the resistance of the patient is the index of prognosis. Properly selected cases should have the benefit of surgery.

Pathogenesis of Skeletal Tuberculosis.—A. Kolodny (*Journal of Bone and Joint Surgery,* January, 1925) notes that the parallelism between the frequency with which certain skeletal regions are involved in tuberculosis and the abundance of their blood supply supports greatly the embolic theory of the pathogenesis of bone tuberculosis. The vascularization of the costal cartilages proves that tuberculous foci in these regions are often of primary and not secondary nature. The anatomical, as well as clinical facts, are in perfect accord with the embolic theory. They speak against the criticism of this theory and against the suggested substitute theories.

Renal Tuberculosis.—M. Persson (*Annals of Surgery,* October, 1925) finds from a survey of cases that the frequency of this complication in men is almost twice that in women. Hereditary tendency can be traced in twenty-five per cent. of the cases. Almost two thirds of the cases are patients in the third or fourth decades of their lives. The cases of localization to the right kidney exceed those of the left. The extent and grade of the bladder tuberculosis seems to have exercised a considerable influence on the final result of the operated cases. In slight ulcerations of the bladder, the late mortality has been almost three times greater than when such have been absent; in extensive ulcerations, the mortality has been extremely great. According to the postexamination of nonoperated patients, unilateral cases have shown a mortality which is but little less than in the whole of the examined nonoperated material, of which certainly almost half, and probably more, have been bilateral cases.

It has been impossible to demonstrate spontaneous healing of tuberculosis of the kidney in a single case. Postexamination of cases treated by nephrotomy and kidney resection exhibit no favorable result. Bad results are also shown after nephrectomy in bilateral cases. The total operative mortality in nephrectomy for unilateral renal tuberculosis amounts to 7.3 per cent.

The best possible operation wound healing appears to have been secured by ligation of the ureter and burning it off by thermocautery below the kidney pelvis, and allowing the stump to drop back, and, fianllay, primary suture of the wound. Abscess formation has occurred in only two of sixty-four cases treated in this way, all of which were followed for a long time after operation. Equally good healing has been obtained, however, in four cases where, after infection of the wound from the abscess contents, a little draining tube has been inserted for the next day or two after the operation. Women, otherwise healthy, who have been nephrectomized for renal tuberculosis, can go through pregnancy and parturition just as well as normal women.

But, on the other hand, if the remaining kidney is affected by a chronic nephritis, pregnancy can lead to exacerbation of the disease.

Medicolegal Notes.

BLOOD POISONING FOLLOWING INJURY TO FINGER

The Pennsylvania Superior Court holds, Felker v. American Chain Co., 84 Pa. Superior Ct. 437, that an award under the Workmen's Compensation Act was properly made where the evidence showed that the deceased had rubbed or scratched his finger during the hours of his employment, that the employment was such that a scratch or puncture of the finger might occur and that he subsequently died of blood poisoning caused by the infected wound. Testimony of a doctor that in his opinion deceased died as a result of septicemia following the injury to his finger was held sufficient to support the finding that he was hurt in the course of his employment.

SECONDARY EVIDENCE AS TO X RAY EXAMINATION

In an action for personal injuries, the Missouri Court of Appeals says, Spellmeyer v. Theo. Hiertz Metal Co., 272 S. W. 1068, that there is room for the position that the interpretation of x ray plates by an expert is the best evidence, and not the plates themselves, since x ray plates must be interpreted and explained by an expert. But, assuming that the x ray plates themselves are the best evidence, where it was established that these were lost and that a diligent search was made for them without finding them, it was held that the trial court properly permitted a physician to testify and state as to his knowledge of the plaintiff's injuries by which he was aided through an examination of the plates, since it is largely within the discretion of the trial court as to when secondary evidence should be admitted.

EMPLOYER'S LIABILITY TO PHYSICIAN

The Oklahoma Supreme Court holds, Farley v. H. T. Milling Co., 239 Pac. 451, that under the provisions of the Workmen's Compensation Law an employer becomes liable for medical fees for an injured employee in one of two ways: First, by contract, either express or implied, with the physician; second, by the physician treating the injured employee when called under the emergency caused by the employer's failure to provide medical aid. In the former case the employer is liable under his contract; in the latter the liability is imposed by law, and the charges must be approved by the State Industrial Commission as a part of the injured employee's compensation, but where the record discloses that no contract, either express or implied, was made for such services, the party rendering such services cannot recover upon contract, and where the record shows that the provisions of the Workmen's Compensation Law have not been complied with, he cannot recover by virtue thereof.

ORDINANCE GIVING CERTAIN PHYSICIANS RIGHT OF WAY HELD UNREASONABLE

The Maryland Court of Appeals holds, Kidd v. Chissell, 126 Atl. 82, that an ordinance which gives physicians with police permits the right of way at street intersections without providing for any means of identifying physicians' vehicles is not a reasonable traffic regulation authorized by 4 Code Pub. Gen. Laws, art. 56, §133.

INGUINAL HERNIA RESULTING FROM STRAIN

The Minnesota Supreme Court holds, Klika v. Independent School Dist. No. 79, 202 N. W. 30, that an inguinal hernia, the development of which is caused by overexertion or strain, is an "accidental injury" within the Workmen's Compensation Act and is compensable. It is held unimportant in the administration of the law whether from a medical or scientific standpoint hernia is classed as a disease or a malformation or is otherwise designated; nor is it important that the employee is predisposed thereto. The law concerns itself only with the legal cause.

QUALIFICATION TO TESTIFY AS TO CONDITION X RAYED

The New Jersey Court of Errors and Appeals holds, Casey v. Atlantic City & S. R. Co., 126 Atl. 293, that it was proper to permit a witness who had qualified as a physician and an x ray specialist to answer a question whether the condition of the plaintiff's injured wrist was such as he would have expected from the condition which he x rayed. He had testified to an external examination of the injury, to having made an x ray of the injured parts, and was being asked to compare the conditions as he found them from both examinations.

FALSE STATEMENTS AS TO MEDICAL CONSULTATIONS

The Minnesota Supreme Court holds, Shaughnessy v. New York Life Ins. Co., 203 N. W. 600, that it is the duty of an applicant for life insurance to give truthful answers to questions relative to medical consultations and treatment. Such matters are material to the risk, and, if the answers are false, the policy may be avoided; but the rule does not require the disclosure of consultations or treatment for slight or temporary ailments. Information possessed by an agent to solicit insurance is not attributable to the insurer, unless the information was imported to the agent in the course of his agency. Answers to questions concerning previous or existing ailments, consultations, and attendance by physicians, and the like, are held beyond the scope of the functions of an agent whose only authority is to solicit insurance. Under the evidence, it was held that there was no room for the application of the rule that, when the applicant correctly states facts to the insurer's agent, who misstates them in the application, the insurer cannot shift the responsibility for the misconduct of its agent.

DAMAGES

The Kentucky Court of Appeals holds, Louisville & I. K. Co. v. Whitesides, 270 S. W. 19, that damages of $2,000 for an atrophied shoulder and forearm, the condition of which would grow worse, were not excessive.

The Texas Court of Civil Appeals holds, San Antonio Public Service Co. v. Alexander, 270 S. W. 199, that a verdict of $21,250 to a skilled mechanic, earning over $300 a month and with a life expectancy of thirty to thirty-five years, for permanent paralysis depriving him of the use of his legs and bladder and destroying his earning capacity, was not excessive.

The Missouri Supreme Court holds, Mattice v. Terminal R. R. Assn., 270, that $25,000 to a fifty year old plaintiff, whose earning capacity had been reduced from $200 to $60 a month by injury to his hand and wrist, destroying the mobility of the wrist and depriving him of the power to grasp anything with his right hand, was excessive in the sum of $10,500.

The Arkansas Supreme Court holds, St. Louis-San Francisco Ry. Co. v. Murphy, 270 S. W. 956, that $12,000 to a brakeman earning $1,500 a year for injuries requiring amputation of three toes, resulting in permanent loss of the use of the foot and injury to the spine, which would probably develop into tuberculosis, was not excessive.

The Minnesota Supreme Court holds, Iverson v. Regola, 202 N. W. 27, that a verdict of $3,000 for injuries to the nervous system as the result of an automobile accident, unaccompanied by any organic injury, was not so excessive as to constitute reversible error.

Cancer—Its Causes and Control

JAMES YOUNG, D.S.O., M.D., F.R.C.S.
Edinburgh, Scotland

I welcome the invitation to write an account of my cancer researches for American readers the more as some of the most valuable of recent investigations have been carried out in American laboratories.

For some years I have been urging that cancer is a parasitic disease and that in the transformation of a normal into a cancerous cell there are concerned, a, the factor that prepares the cell for the action of the parasite and b, the parasite and that only when these two factors are conjoined is cancer possible. I believe that we are within measurable distance of an understanding of the second factor, the cancer parasite. We are still very far, however, from a clear conception of the first factor, the factor that makes for the precancerous cell. As I see it this factor constitutes the major part of the cancer problem and only with a dissipation of the mystery that surrounds it can we hope to arrive at enlightened methods of prevention and cure.

THE CANCER PARASITE

As I have shown in my previous papers (1), published from 1921 onwards, there can be obtained from all classes of cancer, primary, metastatic and transplantable, a microorganism of complex characters. This complexity makes its study a problem of extreme elusiveness and I have suggested that in this fact is to be found the chief reason why the bacteriological investigation of cancer in the past has led to so much divergence of result.

The actual parasitic phase consists of a very minute element living in invisible manner in the cancerous tissue, but in suitable media the microbe emerges from the cell and can then be seen to grow into visible shape. At first it appears as elements which, under the highest powers of the microscope, are just on the verge of visibility. From these there are rapidly formed in the test tube phases of the life story which range in size up to comparatively large microscopic elements. The primitive phase of the parasite consists of a material that is curiously resistant to ordinary stains and often shows up against the dark background in stained films made from an early primary culture as a bright, sometimes refractile, substance. This "cancer plasm" appears usually as globules varying in size from forms just visible at X1000 magnification up to masses twenty micron or more in diameter. They can often be found at the end of twenty-four to thirty-six hours when a piece of cancer is incubated at 37° in any ordinary medium and they can be definitely seen to arise in relation to the cells of the tumor. On rarer occasions this plasm assumes the form of bright unstained rods or filaments and its derivation from the cancer cells can then be recognized in a way which is often very clear.

A study of these appearances thus convinced me that the visible forms of the parasite as seen in the culture medium are derived from an invisible form, probably of the plasm order, which in the fresh cell is locked up in an intimate and invisible manner within the cell substance.

The interpretation which I have put on the facts has been criticized on the grounds, firstly, that globule and rod are merely products of cell degeneration and, secondly, that these socalled plasm elements do not correspond to any form of living matter. The first criticism is met by the fact that similar appearances are not found during the incubation of control tissue and also by a study of the subsequent evolution of globule and rod which I shall refer to in the following paragraphs. The reply to the second objection is that plasm elements can be found in a fluid medium to increase progressively in numbers like any ordinary living body and, as rods, they can on occasion be grown on a solid medium where they produce colonies that develop in the ordinary way. Moreover, that the plasm rod and globule correspond to a living phase in bacterial life is supported by the striking investigations of Löhnis (2) and de Negri (3), who have described similar appearances in other bacteria.

The subsequent development of the plasm forms as this unfolds itself in an ordinary culture medium introduces a series of alternations in form which are extremely confusing and into the details of which I cannot enter in this paper. Briefly the plasm may pass over into a *bacterial* mode of life, in which it takes the form of very minute (Rickettsialike) bodies, of cocci or of bacilli or it may, under other and different conditions of environment, enter on a *fungal* career, when it grows as yeast forms or as branching hyphæ. In my previous papers I have shown that it is certain that some if not all of the various elements that arise from the primitive plasm matrix are capable of living each a true to type life, and that, on the other hand, under suitable conditions of cultivation, one form may be induced to pass over into

Copyright, 1926, by A. R. Elliott Publishing Company.

another form. One of the most interesting and important discoveries made during these investigations was that some of the phases of the microbe correspond to the most familiar types of bacteria. The coccus, for example, is often indistinguishable from a staphylococcus and the bacillus from a coliform organism. The staining and biological reactions exhibit as wide variations as the morphological permutations.

It has sometimes been urged that my views are so opposed to the whole science of bacterial morphology that they must necessarily be based on fallacies of observation or interpretation. Time alone will decide this question. Meanwhile, I believe it is significant that throughout the world a large number of workers are coming to entertain views on general bacterial morphology similar to my own. One of the most outstanding of these bacteriologists is Löhnis (2) of Washington, whose brilliant pioneer efforts in these directions have not received the attention from bacteriologists which they merit. Mellon (4), Almquist (5), de Negri (3), Hort (6), Wade and Manalang (7), Reed and Orr (8), are some among the many other recent investigators whose researches have led to general conclusions that challenge the very foundations of orthodox bacteriology. The general result of all the recent work is to establish with complete certainty that many familiar organisms possess coccal, bacillary and fungal forms as alternative phases in their life story and that in each of these they can propagate themselves in a true to type manner. The extensive investigations of Löhnis and my own observations on the cancer parasite indicate that for the student the secret of bacteriological morphology is to be found in the primitive bacterial matrix—the symplasm of Löhnis or, as I prefer to call it, the bacterioplasm. The discovery of this phase in bacterial life must be considered to mark a new and important stage in the development of the science of bacteriology. The fact, moreover, that in this bacterioplasm we have to deal with a plastic substance in which, as in the germ plasm of higher life forms, we have enchained all the evolutionary possibilities of the race, introduces a new and fascinating subject for the student of evolutionary problems. Meanwhile we can see in it an explanation of many of the striking observations of older workers which were often swept aside by serious investigators as implying nothing but a sort of freak phenomenon. Into this category would fall, for instance, the findings of Henri (9), who isolated from the Bacillus anthracis coccal, yeast and branching threads (1914).

The importance of a new conception in science may be gauged by the degree with which by its aid we can advance to the conquest of fresh fields as also by the way in which, by its means, we can push out into prophecy. For a considerable time I have been struck by the fact that in other types of infective diseases, notably typhus, smallpox and influenza, the confusion and divergence of result associated with their bacteriological study in the hands of different careful workers has exhibited features resembling the confusion that has attended the gropings of bacteriology in cancer. Already my prophecy in respect to typhus would seem to be fulfilled for Weigl (10), Breinl (11), and Fejgin (12), claim to have derived from the Rickettsia of typhus the Bacillus proteus (X19) which has a special relation to this disease.

About the same time as I was carrying on my early investigations in Edinburgh, Glover was arriving by an independent research at analogous results in Toronto. His observations, which have more recently been carried on in New York, ended finally in his describing a microorganism which he was able to obtain from all classes of cancer and which in its essential features is identical with mine. Since then Loudon and McCormack (13) and Scott (14) have confirmed his findings. Within the life story of the Glover microbe, coccal, bacillary, fungal and filtrable elements are found. Moreover, as in my experiments, malignant tumors have been produced in lower animals by the artificial injection of the microbe.

To those who are conscious of the recent tendencies it must be apparent that bacteriology is on the eve of a big awakening, the full importance of which it is impossible to overestimate. One of the most significant of these developments concerns the filtrable viruses. Here again the new morphology has important lessons to teach, for the frequency with which a filtrable form is being discovered as an alternation in the life story of familiar bacteria is of deep significance. Of interest in this connection are the investigations on the Bacillus tuberculosis of Valtis (15), Vannucci (16), Arloing and Dufourt (17), and Durand and Charchanski (18); on the Bacillus typhosus of Hort (7), Almquist (6), and others and on the Bacillus anthracis by Heymans (19). The work of Löhnis suggests that all bacteria may live alternatively in an 'amorphous' and filtrable phase.

The complex character of the cancer parasite, each alternative phase of which is capable of following an independent true to type existence, makes necessary a review of the whole literature on the bacteriology of cancer. For, as I have elsewhere suggested, it is likely that different workers have sometimes been dealing with separate fragments of this complex whole. Such I believe the filtrable forms of Nuzum (20) in 1921 and Gye (21) in 1925 will probably prove to be, as also the bacilli of Ford Robertson (22) (1921) and Blumenthal (23) (1924). Blumenthal has suggested that the bacillus which he has isolated from different types of cancer is not the real infective agent but that this consists of an invisible virus which the bacillus carries. In view of what I have said it would seem likely that the ultramicroscopic virus which Blumenthal finds it necessary to predicate is in reality the parasitic phase of the bacillus and that bacillus and virus are alternative phases of the complex cancer parasite, which I first described in 1921.

The interpretation which I have just given of the divergence in the findings of different workers is in keeping with the morphological study of the cancer parasite and it is supported by the fact that each observer with his own organism has succeeded in producing malignant growths experimentally in lower animals. The results of Glover, Blumenthal and myself are specially striking in this respect.

THE PRECANCEROUS FACTORS

Between the problems of cancer and tuberculosis, as I conceive them, there are striking resemblances. In tuberculosis there is, as the immediate factor, the infecting bacillus, a microbe of wide dispersal in nature. But in tuberculization there are the equally

essential factors that prepare the tissues for infection. Among these we have come to recognize environment (housing, exposure to special forms of ill health, irritation) and heredity. In cancer I believe the problem is essentially of the same order. The cancer parasite, as I have shown, belongs to bacterial types diffusely spread in nature. It is probably even more widely scattered than the tubercle bacillus and it is commonly present on the surfaces of the skin and bowel. An understanding of this fact disposes of one of the greatest objections to the parasitic nature of cancer. It explains how, in the presence of susceptible tissue, the determining cellular infection is easy. So widespread, indeed, must the microbe be that it would sometimes seem that it may almost be disregarded from a mathematical calculation of risks; hence we can explain the hundred per cent. cancers which are sometimes obtained by the experimental tar painting of the mouse's skin. It may, thus, be rightly urged that for the genesis of cancer the "soil" is paramount. For this reason the value of much of the work carried out in the past in disregard of the parasitic causation of cancer is untouched by the discovery of the cancer parasite.

The factor that determines cell susceptibility, namely, the condition of the cell which enables it after infection to embark on the riotous proliferation which cancer connotes is, as I have elsewhere shown, usually a complex of different factors. Some of these are intrinsic and precedent and from the basic cell *anlage* or mosaic on which, as it were, extrinsic and subsequent factors operate. Of the intrinsic ingredients of the cell mosaic, one of the most common is the cellular change induced by *age*. The significance of this factor is well known and I need not refer further to it. Another possible intrinsic constituent of the precancerous cell is *heredity* to which Maud Slye's (24) extensive studies have recently directed attention. A further intrinsic element in the cell, namely an *embryonic or primitive power of continued proliferation,* was recognized long ago as an important factor in cancer as the teachings of Virchow and Cohnheim show. It may be that there are points in common or links or real identity between these varying properties.

The accumulated results of numerous clinical and laboratory observations have established with a certainty that is apparently complete that for practical purposes the dominating factor in the production of the precancerous cell is an extrinsic one, namely, *localized chronic irritation.* Its sinister operations are seen in all classes of cancer where the cancerogenic agencies are observable, e. g., skin, buccal cavity, alimentary tract and uterus, which between them comprise the bulk of human cancer. During recent years it has been established that the cell change is not dependent on the class of irritation; practically any type of local damaging influence may suffice if long continued, e. g., mechanical (sharp tooth), thermal (lip cancer, Kangri cancer), chemical (arsenic, acids, alkalis, paraffin, tar, soot, anilin dyes), chronic infection. For practical purposes the problem has thus gradually shaped itself for the student of cancer into a consideration of chronic sore places produced in the human body by a multitude of irritant agencies. It is obvious that in any community the cancer rate must occur and increase in a ratio determined by the number and the increase of such sore places in the people of that community. When thus formulated, the practical problem becomes disentangled from the theories which have encumbered it and it assumes for us a study in community health which is correspondingly simplified.

ESSENTIAL IDENTITY OF CELL CHANGES PRODUCED BY CHRONIC IRRITATION AND THE EMBRYONIC CELL ANLAGE

In previous papers I have pointed to the evidence indicating that the cancerogenic activity of chronic irritation depends upon the fact that by its means stable and differentiated cells are transformed into cells with the primitive properties necessary before continuous proliferation is possible. In this view, while the riotous subdivision which the cells subsequently exhibit is determined by the intracellular parasite, the precedent persisting damage sets the stage, as it were, for the operation of this parasite. It is obvious that if this conception can be established, it reconciles much of the conflict of ideas which has characterized previous cancer hypotheses by showing that in the ultimate the state produced by chronic irritation and the embryonic *anlage* of the cell are closely related. In its support there are two precise facts. In the first place the regions where chronic irritation acts prominently as a cancerogenic agency are just those regions which are normally covered by a resting differentiated epithelium. In the second place those regions where cancer typically occurs without the apparent operation of chronic irritation are those consisting of cells that are normally primitive, e. g., chorionepithelium. In parasitic plant tumors the same considerations apply for the parasite produces a tumor only when it infects the primitive areas or growing points of the plant. In this connection, crowngall, in which the causal parasite is the Bacillus tumefaciens of Erwin Smith, and warty disease of potatoes due to the synchytrium endobioticum, form interesting studies.

LEUCEMIA AND CANCER

A further proof of the role of cell primitiveness in malignancy is seen in the results of the experimental injection of the cancer virus into *healthy* animals. These results I (1c) have recorded fully elsewhere. Under such circumstances, as we would expect, carcinoma is rarely produced. Out of 270 mice injected, I obtained a local malignant tumor in only five cases. In a large number of the remainder (about thirty per cent.) I obtained, however, a widespread proliferation of the *primitive* cells normally present in the healthy animal. The tissue so affected is the lymphoid tissue of the liver, spleen, lymph glands, bowel, lungs, marrow, etc. In many cases large masses of tumor cells with multiple mitoses are found and there is the frequent occurrence of infiltration of the surrounding structures. In the mild cases the histological picture is that of lymphomatosis or pseudoleucemia, in a marked case of lymphosarcoma. The lesion is undoubtedly due to a diffuse spread of the injected organism and its nature indicates that, whereas the epithelial structures are ordinarily immune (though even here marked proliferative changes are occasionally noted, e. g., in liver), the primitive cells are capable of being stirred to a malign prolifer-

ation. This experimental lesion I first described in 1921. In 1922 Maud Slye (24) described experiments in which she found that in specially reared cancerous stocks of mice, carcinoma, sarcoma or, as an alternative, pseudoeucemia or lymphosarcoma developed spontaneously. She therefore concluded that the latter lesion was a variant of malignancy. My views have received further support by the recent work of Nuzum (20), who found that the repeated administration of the microbe, which he obtains with considerable constancy from human carcinoma, produces in mice a diffuse lymphoid tumor (liver, spleen, lungs, kidney).

These experimental results confirm the view long entertained by many pathologists that the leucemia lesion is essentially neoplastic and must be looked upon as a sarcomatosis. My experimental results led to the study of human leucemia, with the result that in 1922 I succeeded in isolating from the leucocytes in this disease a microbe essentially similar to that isolable from the cancer cell.

NATURE OF THE CHIEF IRRITATIVE FACTORS UNDERLYING HUMAN CANCER

Among all the phenomena associated with the incidence of human cancer there are two that stand out dominatingly. In the first place, the disease is comparatively rare among primitive peoples. In regard to this question there has been much controversy but I believe that the evidence is now overwhelming. It is clear that races that live close to nature are not protected by any special racial peculiarities for when brought into contact with civilization they are found to be prone to the disease. Thus, while the negro races in Africa are practically immune from carcinoma, in the United States there is little difference in the disease incidence of the white and black populations. The same is true of the Eastern races.

In the second place, among civilized races the toll which cancer exacts is enormous and it is increasing with rapid strides, in several countries the death rate in proportion to the living population having doubled in forty years. In England and Wales, according to a Ministry of Health Circular (26), after making allowance for the ageing of the population, the mortality increased from 841 per million in 1901 to 1007 in 1921, or by twenty per cent. In 1923 there were 48,668 deaths from cancer in England and Wales. In the Continental United States the increase was from 47,829 in 1900 to 80,938 in 1922, or per million living from 629 to 868. The difficulties surrounding satisfactory registration in the United States make the general figures somewhat unreliable. In some of the older states, however, this criticism is less applicable and for Massachusetts, for example, the increase per million was from 712 in 1900 to 1166 in 1922. There are considerable differences in the cancer death rates in different countries. One of the most interesting in this respect is Italy, for among large continental countries this stands out as one where the death rate is comparatively low and exhibits little tendency to increase. Thus per million the figures are 680 for 1918 against 650 for 1908. That these figures correspond to some racial habits worthy of close study is demonstrated by the fact that similarly low figures are found in Italian colonies. Thus, as Hoffman (26) has shown in a recent paper, in New York City the Italian rate was only 60 per 100,000 against rates for persons of native origin of 93, of English origin 100, of German origin 115 and of Irish origin 125. Again, in the state of Pennsylvania the native rate was 74 against an Italian rate of only 58. These rates are strictly comparable as they have been adjusted for age and sex. Without drawing any conclusions, Hoffman points to the interesting fact that other investigators have shown that amongst the large European countries the meat consumption in Italy is smallest and the vegetable consumption highest *per capita*.

I have pointed out that human cancer largely resolves itself into a study of chronic "sore places" produced by local irritation. In this view the immunity of the native must depend on a method of life that carries with it a freedom from those factors which in civilized regions promote local irritative lesions. When we approach the question from this viewpoint, which has behind it the sanction of a generation of precise clinical and laboratory research, we are able to formulate the problem in a way that leads to comparatively simple issues. It is sometimes urged that primitive races are protected by some general immunity which is derived from their ways of life and feeding. Although precise data still remain to be gathered more liberally in this field of observation, there is evidence against this view as is shown by a study of such local cancers as those produced by the Kangri basket and betel chewing. Neve (27) of Kashmir, out of 598 cases of cancer amongst the natives, saw only three cases of alimentary cancer and 363 or, if epitheliomata of groin and axilla are included as presumably of the same origin, 451 cases of Kangri burn cancer of the skin. Rentall (28), out of 1482 cases of cancer in Travancore, where the site is mentioned, found 1205 in the mouth, jaw, lip or tongue as the result of betel chewing and only twenty-five cancers in the alimentary tract from the esophagus downwards. These two striking records constitute, as it were, clinical experiments which prove that while irritation is able to provoke cancer in such peoples the irritation is dominatingly external and not alimentary and that, as it were, the circumstances in them are the reverse of those obtaining in civilized races. The facts point with an insistence which is impelling to the alimentary habits of the native as an explanation of his low internal cancer rate. This view is supported still further by the observation of McCarrison and others that, in districts where cancer is rare, appendicitis, colitis and other dyspepsias are also rare.

As I have shown the evidence in favor of a determining local cause in the vast majority of cancers is overwhelming and any hypothesis which refuses to recognize this fact is doomed to failure. At the same time, in the present state of our knowledge we cannot exclude the possibility that in the background there may be other predisposing factors of a general or systemic nature. I have already pointed to the existence of such intrinsic and generalized influences as those implied by age, heredity, etc. There may be others both intrinsic and extrinsic of which as yet we have no clear knowledge. Recently it has been suggested that the high cancer rate among civilized peoples as contrasted with that of primitive races may be dependent on dietetic errors in the former associ-

ated with an impoverished vitamine intake, whereas among the latter this is avoided by the ingestion of large quantities of fresh food. It is impossible to pronounce any definite opinion on this view, which has recently been strongly urged by Ellis Barker (29), until we have acquired more precise data. Meanwhile it may be pointed out, however, that such data as those relating to the incidence of Kangri and betel cancer are apparently opposed to this explanation in so far as they emphasize the purely local viewpoint. The same arguments may be opposed to such views as that of Ross who attributes cancer to a defective potassium intake. At the same time it cannot be denied that there are some facts which can be more readily explained on the assumption that generalized factors of extrinsic origin as well as local factors may be present; for example, the way in which the incidence of increase so prominent during recent years tends to affect widely scattered organs and areas in the body. It is therefore important that with our attention focused on the local causes we must not shut our eyes to the possible and even probable operation of some generalized agencies which, in an increasing degree, are conspiring to make the peoples of civilized communities more liable than their predecessors to suffer from the damaging effects of tissue irritants.

Even after we have given to such considerations their full weight, however, we can be left with no doubt that the problem of immediate practical import is irritation and that this may be localized to one organ and in it provoke cancer when there is no evidence of altered vitality elsewhere in the body. The facts on which this conviction rests are at once a challenge and a hope for they point to a very precise field for observation in which every new discovery will bring us nearer to essential causes which are extrinsic and avoidable. Where the issues are clear, as in occupational cancers, e. g., in paraffin workers, mule skinners, etc., public health effort is comparatively easy. Despite the consideration that in the alimentary types, which comprise the bulk of human cancers, the causes are still elusive, the fact that they must begin as chronic sores due to long standing local damage, means surely that their origins are detectable if only we apply ourselves to the facts. I have shown that all the evidence indicates clearly that the absence of alimentary cancer in primitive races must be due to alimentary habits that are unassociated with local irritation of the mucous lining of the digestive tract and that, *per contra,* the large incidence of alimentary cancer in civilized communities must be due to alimentary conditions that provoke irritation. It is necessary to reiterate these simple facts for I believe that, more than anything else, a failure to grasp their significance has in the past militated against the development of the clear cut outlook necessary for a successful prevention. For with a recognition of these issues it becomes apparent that in the ultimate the most important of all the classes of human cancer can be traced to considerations of *diet.* If, as I believe is possible, we can establish this proposition there at once emerges a great fact that will give to the anticancer crusade a momentum of tremendous force. That anticancerous developments along these lines are well advised is strongly supported by the fact that the tragically rapid increase in all types of internal cancer among civilized peoples coincides with changes in their dietary which have called forth the repeated warnings and protests of those qualified to speak with authority. Many have pointed to the fact that this increase has coincided with a great augmentation in the consumption of canned food and of food doctored by preservatives and have suggested that there is some corelation. This is a line of inquiry worthy of consideration. We have to remember, also, that food irritants are probably as numerous and as varied as the multitude of irritants that can provoke external cancer. While it would be foolish to insist that civilized man in order to escape the menace which he is raising for himself must revert to the rough and crude dietary of his cancer free brother in the wilds of Africa or the barren plains of India, it is urgent that he recognize quickly that his disregard of the most important of all the things that make for physical well being is leading to disaster.

We can thus see emerging from the confusion of theories which has encompassed cancer a clear direction for preventive work. We cannot say that such and such a food irritant is specially responsible for cancer, but we can say with confidence that any food irritant whatsoever is suspect and we can with a certain conviction teach the people that by the practice of the well recognized principles of a simple dietary they can do much to avoid the most frequent kind of all human cancers. To have the greatest possible effect the observance of enlightened hygienic rules must commence in infancy for, as Arbuthnot Lane (30) and others have shown, bad alimentary habits started in early years may lead to permanent mechanical damage of the bowel, associated with bands and kinks and with a chronic intestinal stasis and irritation, that in later years not only cause cancer but determine the sites. I believe there is no more convincing testimony to the fundamental errors of our diet and the early age at which these commence to operate than the widespread dental caries of civilized communities. This stands forth as probably the most obvious monument to the hygienic ineptitude of the times.

CANCER CONTROL

I have already referred to the big opportunities we have for preventive work. We may look forward with confidence to an early eradication of occupational cancers. By preaching the gospel of a simple diet we know that we are getting to grips with the greatest menace of all, namely, alimentary cancer and, if Arbuthnot Lane's views are correct regarding the localized damage which circulating intestinal poisons can inflict on the breast and other organs, the practice of sound dietetic and alimentary habits will strike widely at the spreading roots of the greatest canker of civilized times.

Cancers in other sites can be prevented by attention to the corresponding local irritations, in the case of buccal cancer by the avoidance of sores from smoking, jagging teeth, badly fitting dentures or oral sepsis; in the case of uterine cancer by the avoidance or treatment of cervical lacerations, and so on.

Pending the discovery of a strictly scientific cure of the disease we can make more widely known to doctor and public alike the very considerable chances there exist of a complete cure by surgical means and the fact that these chances in some regions, lip,

tongue, breast, uterus, etc., rise to figures ranging from fifty to one hundred per cent. when the disease is treated early. After all the cure of any disease is always a relative matter. There are few diseases where cure is certain and there is no grave disease where, as in cancer, a purely local origin allows of early and complete extirpation. Thus in early cases of cancer of the lip the Mayo Clinic (31) shows ninety per cent., and the Johns Hopkins Hospital (32) (Bloodgood) ninety-five per cent. five year cures. The statistics of the Johns Hopkins Hospital (33) extending over a period of twenty-five years show that in early cancer of the breast where there is no involvement of the axillary glands the cures are seventy per cent., and the same hospital (34) in early cases of tongue cancer shows a sixty-two per cent., five year cure. Similarly in early cancer of the cervix the five year cures may be as high as fifty per cent. (Bonney 35). Recently there have appeared a number of records which suggest that with radium very striking results may be obtained in cervical cancer. Thus Heyman (36) has published an account of 40.5 per cent. five year cures in operable and borderline cases, while at the Doederlein Clinic at Munich, in clearly operable cases, the five year cures were 48 per cent. and, in those who completed the radiation treatment, 80 per cent. (thirty-five out of forty-three) (39).

There is thus ample evidence to justify our carrying a message of hope to the public and we can emphasize this message in respect of accessible cancers, but at the same time it is our clear duty to make plain to them the early warning signals of the disease so that treatment can be established without delay. Much has been done in this way but much more remains to be done through the medium of the medical practitioner, the press and the platform. In the United States gratifying results have followed the propaganda of the American Society for the Control of Cancer and other agencies. In discussing this question Bloodgood states that the effect in bringing patients earlier for treatment is almost incredible. Thus at the same clinic in the decade 1890-1900 in breast cases there was usually the history of a long duration of the disease and eighty-five per cent. were cancerous, whereas during the years 1920-1922 when there was a lump it was cancerous in only fifty per cent. Even more striking was the fact that, while in the first period only one per cent. were able to be dismissed without operation, latterly fifty per cent. were so dismissed without operation, thus showing how alive the public had become to the need of early advice. In regard to tongue cancer, also, Bloodgood says that the educational propaganda has increased the number of operable cases at his clinic from fifty-three to eighty per cent. and decreased the number of hopeless and inoperable cases from forty-seven to twenty per cent.

The initiation of a cancer week in some centres with an accompanying intensive press campaign has succeeded beyond the hopes of the promoters. Thus Saltzstein (37) reports that in Detroit during four days 1100 people applied to eight hospitals for advice about sores, lumps, etc. and out of this number forty-two cancers were discovered clinically and seventy-five precancerous lesions. The cancers included the following regions: face, seven; lip, four; breast, sixteen; uterus, eight; etc. McCalla (38) of Idaho likewise reported that during National Cancer Week in seven small communities in Idaho 108 cases of early cancer were discovered. These results are heartening and they exhibit clearly how with a widening of the campaign and the recognition and treatment of precancerous lesions many can be saved from developing cancer and many thousands can be rescued even after they have fallen into its clutches. The education of the public along well planned lines, moreover, will remove much of the fatalistic attitude towards the disease which is often based upon the false belief that it is invariably incurable.

Mouth Infections; Their Symptoms and Immediate and Remote Effects*

J. L. T. APPLETON, JR., M.D., DD.S.
Philadelphia

A debit and credit philosophy is instinctive with most human beings. This attitude is reflected in most religions which hold forth an immortality or at least a life after death. Compensation for the sorrows and toils of this life will be found in the joys of a posthumous existence. Poverty, at least in our sentimental literature, has certain advantages over wealth. Brain power and muscle power in the same individual sometimes rather conspicuously stand in inverse relation to each other. The invalid occasionally finds a peace which her aggressive, robust brother misses. The acuteness of the senses of hearing and touch are proverbial in the blind. Instances of this nature can be multiplied *ad libitum*.

Somewhat over a hundred years ago this viewpoint came into biology as the *loi de balancement*. Goethe and the elder Geoffrey St. Hilaire independently had noticed that at times marked structural specialization along one line appeared to be secured at the expense of other parts. A gain was balanced by a loss.

Now, in modern biology not too much stress is layed on this *loi de balancement*. Darwin (1) admitted there appeared to be some evidence for it but it must be applied with restraint and discrimination. At any rate it seems to serve admirably to introduce our subject upon a broad background of general biology.

The moet distinguishing peculiarity of man is his extreme cerebral development. The disproportionate growth of the cerebral hemispheres has required a commensurate growth of the cranial part of the skull. This has been accompanied (perhaps compensated for) by certain changes of an atrophic or degenerative or retrogressive character in the facial part of the skull. Among these changes are a shortening of the body of the mandible and lessened room for the eruption of the teeth. There is also paleontological evidence that man's teeth are falling into the category of superfluous and useless organs and it is common experience that such organs are more liable to ills than organs important for the survival of the species. Organs, retrogressively rudimentary and relatively unnecessary for the life of the individual, are not kept toeing the mark by the action of the struggle for existence and the elimination of the unfit. Perhaps the toothlessness of senility, immortalized by Shakespeare (2), will turn out to be a prophecy fulfilled in the old age of the race.

In addition to these evolutionary handicaps, man's mental development has indirectly worked further harm to his dental heritage. We have all heard of unfortunate individuals who had champagne tastes and beer pocketbooks. This discrepancy is no greater than that which habitually exists between the gastronomic proclivities of civilized man and what his body really needs in the way of food. It is unnecessary on this occasion to particularize, but we can admit that the dietary habits of the vast majority of civilized men are not suitable to the capabilities and needs of the human body.

In brief, to outline my argument so far: As a result of evolutionary processes leading to man's cerebral specialization man's teeth are in various and for the most part still obscure ways faultily developed. This same cerebral specialization has rendered man's survival relatively independent of his teeth, which consequently become liable to the vicissitudes of rudimentary organs. Again, this cerebral specialization by influencing man's dietary habits has affected the body's metabolism to the disadvantage of the teeth.

If the viewpoint developed in the preceding paragraphs be correct, then to the eyes of the pure biologist or evolutionist the work of the dentist is futile. He is kicking against the pricks. If fortunately from your own experience you knew nothing about it, you could infer from what I have said that disease in the mouth is not uncommon. It seems as if from a number of circumstances the cards were stacked or the dice loaded against the health of the teeth and their adjacent parts. If I left you here you might well be pessimistic. But as a dentist I must try to justify my professional existence. We, both you and I, are (as Roosevelt once wrote) practical men, and must give ear to the expediencies of the moment. The detached or abstract attitude of the pure biologist or evolutionist, however useful, is nevertheless an artificial, formal attitude. The problem of the moment, of the present generation and its children and grandchildren, is really more urgently important to us than the ultimate fate of the human race. An ever present problem is that of disease, and it would be illogical and shortsighted to ignore disease in the mouth.

There are three infections or infectious conditions to which I wish to direct your attention: periapical infection (i.e., infection around the end of the root of a tooth), periodontal disease (commonly termed pyorrhea alveolaris) and Vincent's stomatitis or trench mouth.

Periapical infection almost invariably is a sequel to the decay of teeth. Enamel and dentin have been destroyed, the pulp killed and the bacteria following this path have reached the periapical tissues. At this stage the patient may or may not experience more or less local pain or tenderness. The tooth may to the patient appear longer than its neighbors. Or the patient may have no inconvenience. The electrical and thermal conductivity of such a tooth is lowered. Examination of the affected part with the röntgen ray may, except in acute cases, show evidence of the absorption of lime salts from the involved periapical region. Röntgen ray examination is, all things considered, the most practicable way available as yet to obtain an insight into the periapical condition of a suspected tooth. There are however certain limitations. In the first place the negatives must be in-

*A lecture given in a series on Timely Phases of the Public Health Problem, under the auspices of the School of Hygiene and Public Health of the University of Pennsylvania.

terpreted by a man with large special experience, thoroughly familiar with the normal forms and relations of the parts involved. In the second place it must be remembered that the röntgen ray never can reveal the presence or absence of infection. It can only show the presence or absence of bone absorption. If we find röntgenographic evidence of periapical bone absorption, we usually infer the presence of infection, but the fact should be kept in mind that periapical bone absorption can be occasioned by purely mechanical strains and stresses.

The symptoms of periodontal disease (pyorrhea alveolaris) are soft, swollen, bleeding gums, the formation of pockets around the roots of the teeth, the flow of pus from these pockets, the denudation of the roots of the teeth leading at times to an unpleasant sensitiveness toward extremes of temperatures or certain foods, the loosening of the teeth occasioning more or less pain on chewing, and disagreeable or offensive breath odors, whose antinuptial properties are well known to all students of popular advertising.

The symptoms of Vincent's stomatitis or trench mouth are purplish red, swollen, easily bleeding gums on which may be a thin, easily removable grayish membrane or large, shallow irregular ulcers. The gums are ordinarily exquisitely painful and the odor of the breath is peculiarly sickening and offensive. Vincent's stomatitis is usually an acute condition, while the majority and most significant of the periapical and periodontal infections referred to above, are or become chronic.

The immediate effects, in both the spatial and temporal senses of the word "immediate," are rather trivial in comparison with the remote effects. Periapical infection often causes no immediate inconvenience. Mastication may be slightly interfered with.

In the case of periodontal disease the patient may experience considerable local trouble from the pain and difficulty of chewing and from the sensitivity of the denuded roots. If the disease be allowed to progress and also too often in spite of treatment, the teeth become so loose as to drop out of themselves or to be pulled out by the patient with his fingers.

In well marked, acute cases of Vincent's infection the gums are often so sensitive that no mastication of food can be done. Even the involuntary or unconscious movements of the lips and tongue are most painful. At times, if allowed to progress, the alveolar process in spots may be exposed by the destruction of its overlying mucosa and the teeth may drop out.

From your point of view I believe the remote effects of these infections to be most interesting. Of focal infection I shall say little because it is not, at least in medical and dental literature, a neglected subject. For sake of completeness I need only remind you that periodontal and particularly periapical infections have been held responsible for a great variety of pathological conditions, e.g., some cases of secondary anemias, arthritis, myositis, endocarditis, gastric and duodenal ulcer, cholecystitis, appendicitis, iritis, neuritis, neurasthenia and some psychoses (3).

The evidence that oral infection may act as a focus from which bacteria and their products are distributed through the body, may be summarized as follows:

1. The same bacteria which are found at the focus have in some instances, been recovered from the remote lesions. The streptococci almost exclusively are of significance in focal infection as understood here.

2. The bacteria isolated from the focus when injected into susceptible animals will sometimes bring about a condition in the animals similar to that seen in the patient.

3. The elimination of infection at the primary focus is in some instances followed by amelioration or cure of the secondary condition. The failure of improvement in such a circumstance does not definitively weigh against the doctrine of focal infection. If bacteria have successfully colonized at the site of the secondary lesion, e.g., in a heart valve, their removal from the primary portal may prove unavailing.

4. The administration of autogenous vaccins prepared from bacteria isolated at the primary focus, may call forth symptoms at the sites of "secondary" localization, e.g., in a point.

5. When the primary focus is subjected to surgical trauma, as in dental extractions, there sometimes occurs an exacerbation of the "secondary" condition.

In speaking of oral infectious foci, it should be kept in mind that chronic infection elsewhere in the body, as e.g., in the tonsils, the postpharyngeal lymphoid masses, the nasal sinuses, the middle ear, the gallbladder and vermiform appendix, the colon, the prostate and the tubes—may bring about identical results. We have no data which will permit us to draw a reliable conclusion as to the relative importance of these several infectious foci. Probably current general medical opinion gives first place to tonsillar infection. To maintain a sane perspective the Latin motto on our commonest coin should be applied to the mouth as an infectious focus—*e pluribus unum.*

Only one more remark about oral focal infection in the narrow sense of this phrase—many, in fact most, individuals from early middle age on, harbor chronic infection in their mouths through many years apparently without suffering any harm. I wish to stress the word apparently, with the mental reservation that "appearances are sometimes deceiving."

The significance of Adami's (4) conception of subinfection has not been sufficiently appreciated in this connection. The tissues of the body in health are potentially sterile not invariably actually sterile. Even though bacteria be entering the body they are being destroyed at least as rapidly as they enter. If with recurrent invasion the tissues become worn out, chronic or acute infection may supervene. Other things being equal, it is conceivable that the more bacteria which enter in a given time, the more rapidly will the tissues be worn out. The bacteria which continuously or periodically invade the body from chronic periapical or periodontal infections or the toxic products which diffuse out from these foci may be destroyed—but their effects accumulating through years cannot but be harmful to the host. When for any reason the local resistance of an organ or part

or the general resistance be lowered, some of the bacteria entering from these foci may survive and serve to establish secondary localizations. The infectious foci in themselves acting as subinfections, tend to lower the resistance of the body and in this way a vicious circle is established.

I have deliberately condensed our consideration of oral focal infection to very narrow limits. The subject has been a popular one for some time and there is nothing materially new that could be brought you. There are other phases of oral infection which are not unimportant and which are less appreciated.

In pulmonary tuberculosis the establishment and maintenance of oral health will practically eliminate the tubercular localizations which at times occur on tongue, gums and buccal mucosa. The mechanism of their origin is simple, being just the implantation of tubercle bacilli from the suptum upon preexistant wounds. Pyorrhetic pockets constitute such wounds (5). Such cases are however very rare.

A much more important relation of oral infection to pulmonary tuberculosis arises from the inspiration of Vincent's organisms and the common pyogenic cocci from a diseased and neglected mouth. We have such opportunities offered in the common periodontal infections, in gingivitis, and in Vincent's stomatitis. Pyogenic infection secondarily implanted upon an already existent lesion of tuberculosis in the lung will facilitate cavity formation and the distressing and discouraging febrile complications. When the secondary invaders are the Vincent's organisms the result is the more serious, putrid and gangrenous processes, which often run a rapid and fatal course. From what I have said, it is not acting with the highest degree of intelligence to ignore the condition of the mouth if our aim is to permit the patient to mobilize all his defensive and recuperative resources against the tuberculous infection.

The oral manifestations of syphilis are classical and do not call for exposition here. There is only one point of which I wish to remind you in this connection. When mercury is used for treatment, it can be administered far more intensively when attention is given to the health of the mouth. Not so long ago the state of the mouth was the guide followed in this form of treatment. The physician would push the mercury until the patient's mouth became so sore he could stand it no longer. Then the mercury would be suspended until the mouth returned somewhat to normal, when mercury would be given again. This alternation could be repeated indefinitely at the option of the physician and the patience of the patient. It is a well established fact that appreciably larger doses of mercury can be given before mercurial stomatitis appears if the mouth be well cared for and kept in a healthy state.

An occasional recent report suggests that a somewhat analogous condition may occur even in the administration of the organic arsenicals (6).

In several respects the oral condition of the patient is of importance in general surgery. In the case of postoperative pneumonia many factors are operative, but the great predominance of type IV pneumococci (7)—the ordinary pneumococci of the mouth—supports the view that we are dealing with an aspirational form of pneumonia. Periodontal disease, gingivitis and stomatitis in proportion to their severity and extent furnish larger numbers of bacteria and under these conditions the aspiration of a minimum infective dose will be facilitated. In some hospitals it has been definitely found that the incidence of surgical pneumonia is lowered among those who have had their mouths freed from gross sepsis previous to general narcosis.

The similarity which exists between postoperative pneumonia and terminal pneumonia, suggests that the arrival of this latter condition may be postponed by cutting down oral infection to a minimum. The mouths of the aged or of those long bedridden often are in a deplorable state. Even though in the true sense of the word Osler's characterization is just—and terminal pneumonia often is "the old man's friend," still the irony of life is such that the patient himself and his relatives many times would welcome anything which delayed the arrival of such a friend.

In the case of postoperative parotitis the bulk of recent and current evidence (8) is in favor of regarding this serious and distressing complication as an infection ascending along Stenson's duct. Any surface oral infection, as pyorrhea alveolaris or stomatitis, will increase enormously the number of pathogenic bacteria which in this way can reach the parotid. With this in mind it is obvious that attention to the health of the mouth is indicated as a prophylactic measure. It seems a rational precaution to urge, not only against postoperative pneumonia and postoperative parotitis but as a measure based on general principles, that in all but emergency cases the mouth be put in a state of health as a routine procedure before major surgical operations.

Whatever be the cause and nature of gastric ulcer, it is certain that this lesion will be aggravated by being bathed with a suspension of pathogenic bacteria. Kopeloff (9) has shown that the bacterial content of the stomach is largely determined by the bacterial content of the saliva. Consequently the greater the infection in the mouth the greater will be the irritation offered to the gastric ulcer.

In all cases in which the gastric secretion is deficient in its hydrochloric acid content or in which an absolute achlorhydria exists, it is particularly desirable to cut down oral infection to a minimum. This is to avoid intestinal infection. It has been repeatedly shown (10) that the germicidal value of the gastric juice is essentially a function of its hydrochloric acid content. It has been pointed out by Hurst (11) that oral sepsis and achlorhydria are constantly associated with Addison's anemia and subacute combined degeneration of the cord. Streptococci are found in the duodenum of such patients. Hurst is also of the opinion that achylia gastrica may predispose to appendicitis or cholecystitis by permitting the access into the intestinal lumen of large numbers of pyogenic bacteria. In this connection it is not amiss to note that some evidence (12) has been presented indicating that oral infection predisposes to cancer of the alimentary tract and associated parts and also, that neglected oral sepsis shortens the duration of life of patients affected with alimentary carcinoma.

It has long been recognized that diabetes mellitus predisposes to infection, particularly with the com-

mon pusproducing bacteria. The dentist has known this and when a case of pyorrhea alveolaris is unusually resistant to ordinary treatment the patient is sometimes found to be a diabetic. In this disease the power to form antibodies is reduced. The bactericidal properties of the blood in dogs were found by Sweet (13) to be definitely diminished after excision of the pancreas. Da Costa and Beardsley (14) in natural human cases found a subnormal opsonic index, which was particularly low in the more severe cases studied. Takimura (15) observed a marked depression of the phagocytic power of leucocytes at least toward the tubercle bacillus in the serous fluid of the thoracic and abdominal cavities of diabetic rabbits. Under these conditions it is obviously unwise to temporize with oral infection of any type.

Since the advent of insulin another relation between infection and diabetes has been discovered (16). A general and local bacterial infection is often the immediate cause of the onset of coma and in the presence of infection, insulin is much less effective in lowering the blood-sugar. The cases cited as illustrating these phenomena, so far as I am aware, are not cases of oral infection. Although I can see no reason why oral infection should be an exception, still it will be necessary and interesting to observe the influence of the elimination of oral sepsis on diabetes mellitus.

In conclusion I wish to follow in one particular the example of Cato the Censor. So impressed was he with the threat which Carthaginian prosperity offered to Roman dominance that he ended all his public addresses—no matter what the topic, whether prohibition or the income tax or the morality of hair bobbing—with one stereotyped phrase—*Delenda est Carthago,* Carthage must be destroyed. In my humble way when I am talking shop and whenever the opportunity offers, I like to wind up with some such saying as—Oral Infection Must Be Prevented. I am not altogether sure that this is really the anticlimax Cato would have thought it to be. After chronic periapical and periodontal infection has once been established the best that can be done is in the nature of a compromise, the making the best of a bad job. This is said not to encourage an attitude of fatalistic resignation but to urge the necessity of preventing mouth infection.

The author's references will appear in his reprints.

The Inheritance and the Medicolegal Application of the Blood Group

J. ARTHUR BUCHANAN, M.D., M.S.

Brooklyn, N. Y.

(*Concluded from page* 300)

While black may be the absence of white, the presence of white in the germ plasm had to be an actuality before it ever occurred in the somatoplasm of the zygote. The presence and absence theory is reducible to an axiom which states, that only one object can occupy the same space. A character may be absent in the somatoplasm, but present in the germ plasm, and this presence and absence in the same individual gives a hybrid.

The evidence available is indicative of the union of agglutinogens and agglutinins in such a manner that neither is separable from its mate in the germ plasm, and that the determiner for each blood group is unchangeable in the germ plasm. If one of the doses for a group is replaced in the germ plasm, it is replaced as a whole and not for a segment of the group as it appears in the zygote. A study of three generations indicates this conception to be correct, and furnishes data which demonstrates the falsity of the assumptions that have heretofore been made concerning the origin of groups different from those of the parents.

The significance of considering each blood group as specific is illustrated in a study of the results from crosses of Group I (*ab*), and Group II (A*b*). If the hybrid stage of man were present all crosses of *ab* with A*b* should give offspring that are A*b* as the evident unit character, and *ab* as the dormant character, as the *ab* has been supposed to be recessive to the A*b*. A second mating from offspring of this cross in which the germ plasm would have the constitution of A*b ab* should result in the segregation of A*b* (pure Group II), Ab ab heterozygous Group II), and *ab* (pure Group I). What actually happens when a Group I is crossed with a Group II? The family of Keyne (8) may be used as an illustration, or the third and forty-seventh families of Ottenberg. The cross of Keyne's family resulted in four children in Group I, and one child in Group II, and comparable results are seen in both of Ottenberg's families. This is the very reverse from what is to be expected from the cross of dominant and recessive characters. The immediate segregation of the characters represented in the parents occurred in the families cited. Anyone at all familiar with the primary significance of Mendel's studies on hybridization would know that a portion of the four Group I children were heterozygous to Group II, and that unions of these Group I children with other Group I children resulting from a similar cross could legitimately have both Group I and Group II children. If such were not the case the blood group would not follow the first law of Mendel, namely, that the characters represented in the germ plasm and samatoplasm of the cross breed reappear in the offspring of the cross breed. I have found authentic families in which there was no possibility of mistake or illegitimacy in which unions of Group I resulted in children in groups other than Group I; in fact in different crosses Groups II, III, and IV have appeared, and the ancestry in each case made such an occurrence possible and reasonable. The mere finding of such

families is to demonstrate the constant nature of each blood group and the transmission of the unit factor for each blood group between generations by the germ plasm.

The family of Keyne's contains other illustrations of the expectations from crosses of the blood groups. The family, by the way, is not indicative of the same type of material as that in the Tink family of my observations. The only relationship between the family heads in Keyne's family is the union of a Group IV with a Group I person. This is not representative of the blood group pedigree of a single family, but is representative of two families that have intermingled at one radical. Regardless of this deficiency, the family contains an excellent illustration of the value of a three generation study, where only a portion of the possible results are given. The cross of Group II (A*b*) with Group IV (AB) furnishes the data. The Group IV contains theoretically both dominant characters, while Group II contains theoretically one dominant and one recessive character. Regardless of this, the offspring from the cross, if the first filial generation were present, would all consist of individuals in the same blood group, providing the parents were homozygous. The cross resulted in one child in Group II, and two in Group IV. If the blood group follows the Mendelian laws the constitution of the offspring are pure Group II, pure Group IV, and heterozygous Group IV/II. The next generation consists of a cross of a Group IV person with a Group III person. There was one child in Group III, and three in Group II. This is just what is to be expected from a character following the law for the segregation of characters. The Group IV was heterozygous, and no facts are presented to prove the heterozygous or homozygous nature of the Group III parent. On account of the rarity of Group III, it is particularly difficult to secure a cross of pure strains of Group III although Ottenberg reported one satisfactory family in 1908 (9). The cross of the Group IV with Group III is still further proof that the hypothesis of Ottenberg that the study need only be carried into two generations is incorrect. On account of the specific nature of all hereditary characters, there is no possible source by which the agglutinin *b* of the Group II individuals could have been introduced into the result of this cross when there was no agglutinin *b* in either of the two parents, unless its determiner was present in the germ plasm. A review of the preceding generation, however, shows the source of the agglutinin *b* was really in the A*b* of a grandparent, and demonstrates that the Group IV parent was a heterozygote with a germ plasm constitution of AB (IV)/A*b* (II). Of course, if the claim is made that the agglutinins are not inherited, but may occur at random, the situation is changed. Ottenberg says that what really is inherited is the presence or absence of the several agglutinogens; that this presence is "dominant" and this absence "recessive" as defined by Mendel. In the cross of Group I and Group II the absence of the agglutinogens certainly behaved as a dominant character, at least the numerical supremacy of the supposed dominant character is not demonstrated. There is no hybrid to show which side of the character appeared during the first filial generation. Ottenberg shows the above to hold true in his third and forty-seventh families. An analysis of the data presented by Ottenberg from crosses of individuals containing dominant and recessive characters shows that the agglutinogens do not behave as dominant characters. In the groups in which agglutinogens and agglutinins occur they exist in a state of genetic equality and are transmitted as inseparable entities between generations.

The relationship of agglutinins and agglutinogens in the groups in which both occur, is shown by available data to be comparable to the relationship of the petals and sepals of a plant. Petals and sepals have different functions but they are biologically, in the same plant, inseparable. The laboratory experiments conducted to show agglutinins and agglutinogens as independent units are comparable to pulling either the sepals or petals from a flower. If the reproductive organs of the flower are left intact, future offspring from the plant will have the same number of sepals and petals in exactly the same relationship as those of the parent, or present a presence or absence of either sepals or petals according to the fundamental structure of the plant. The test tube experiments on the blood groups in no way demonstrate the nature of germ plasm determiners for the blood groups. The laboratory data do not indicate the breeding possibilities of parents in the different groups.

Hereditary characters are constants, and the determiners for the characters are constants. The determiners are not changeable in the germ plasm, but exist there purely in a state of association. Immediately upon crossing mixed individuals the characters introduced reappear. Available data in the various fields of studies in heredity justify the conclusion that agglutinogens and agglutinins present in the parents are not rearranged in the germ plasm to give a blood group in the offspring different from ones in the parents. Crosses of Group IV and Group I do not give Group II and III offspring because the A, B, and *a, b* are twisted about to give the groups mentioned. If such were the case crosses of Group IV and Group I would always give this result. Crosses of Group IV and Group I only have Group II and Group III children, when they are heterozygous for these groups. A review of more than two generations is necessary to dispel the mystery.

Although the specific agglutinins of Groups II (*b*) and III (*a*) may be the two radicals that unite to give Group I, they have in the union in Group I properties not possessed by either of the agglutinins when existing separately. There are numerous similar situations in chemistry, and although two elements combine a third substance is actually formed. The same applies to the agglutinogens. For this reason I feel that the conclusion of Moss that there are three agglutinins and three agglutinogens remains uncontradicted.

If the constitution of the various blood groups is recognized as specific, namely, Group I, *ab;* Group II, A*b*; Group III, B*a*; and Group IV, AB, and the blood group conceded to depend upon a specific determiner for each blood group that is unchangeable and unalterable in the germ plasm, the letters may be used in the combinations given to fulfill all of the genetic possibilities in conformity with the two laws of Mendel, as well as the laboratory experiments conducted to prove the existence of agglutinins and agglutinogens. These letters are purely symbols for

I, II, III, and IV, so that it makes little difference whether they or the numbers for each group are used. The concrete entities for which they stand have not been visualized. The germ plasm is considered in all instances to contain two doses for each character. The germ plasm constitution of each individual pure for the blood group is *ab/ab*, (I); A*b*/A*b*, (II); B*a*/B*a*, (III); and AB/AB, (IV).

MAN IS NOT DIHYBRID

The suggestion has been made that "Man, in relation to the isoagglutinogens and isoagglutinins is a dihybrid." A few simple illustrations show clearly that man is not always hybrid for these substances. If Group III individuals be taken as an illustration of the supposed dihybrid status of man, a study of the result of crosses of Groups III and III will clear up the situation. Crosses of Group III, if it is considered a dihybrid, would be comparable to crossing hybrids of the first filial generation of plants and animals. The result would be twenty-five per cent. homozygous individuals from the dominant character, giving a group (B) for which there is no terminology at this time; fifty per cent. of dihybrid Group III (B*a*); and twenty-five per cent. which would possess another group made up of the recessive character (*a*) of the dihybrid. There is no group to constitute the recessive character (*a*). If the formula B*a* is used to indicate Group III in the germ plasm, it would always be expressed as B*a*B*a*, unless the individual in Group III is heterozygous and then one half of the germ plasm for blood group will be taken up by the determiner for the group for which the individual is heterozygous. A quarter of the germ plasm for a group is not split off in the germ plasm and replaced by a quarter from another group to give the group of the zygote. One half of the germ plasm has always been considered replaced by the second germ plasm property.

Hybrid matings always give the same result, and the perpetuation of hybrids exclusively by mating hybrids is the antithesis of Mendelism. No one has ever stopped to ask if agglutinin *a* is recessive to agglutinogen A and *b* is recessive to B, what the genetic relationship of *a* is to B, *b* to A, *a* to b, and A to B. The law for segregation answers these questions; and demonstrates that there is a fixed relationship between the specific substances. An analysis of the constitution of either Group I or Group IV gives conclusive data.

1. *ab/ab*×*ab/ab* equals *a/a*+2 *ab/ab*+b/b.
2. AB/AB×AB/AB equals AA+2 AB/AB+B/B.

Both crosses would give groups that have never been observed. The analysis of crosses of Groups II and III respectively show that there is no character relationship of *a* to B and *b* to A.

An analysis that applies to Group III, applies equally as well to Group II, as it is supposed to consist of a dominant and recessive character. Unless the factors for unit characters are represented in the germ plasm of parents they never appear in the offspring.

The agglutinins are not mere pawns but represent as distinct qualities of the serum as the agglutinogens do of the red cells. Group I, Group II, Group III, and Group IV may be crossed with their respective group, and all the children that result from the cross be in the same group as the parents. Such families definitely disprove for all times the dihybrid suggestion.

RELATIONSHIP OF BLOOD GROUPS IN GERM PLASM

The determiners for the blood groups, so far as information is available, behave in the germ plasm as allelomorphic characters behave in the hybrid state of plants and animals. Therefore, it is possible for the germ plasm of a parent to transmit not only a character present in the blood stream, but also another character or blood group that is represented by a determiner in the germ plasm. In other words from any cross of two individuals in different groups, it is possible for the children to be in any or all of the four blood groups provided the germ plasm contains determiners for different dormant groups, but if dormant groups are the same, only three different groups can occur. Crosses of parents in the same blood group can never have legitimate children in more than three different groups. Legitimate children with agglutinogens can result from parents without agglutinogens in the blood stream and, furthermore, children with agglutinins can be born legitimately to parents without agglutinins in the blood stream. All the evidence proves that agglutinogens are not dominant to the agglutinins. If the agglutinins were recessive to the agglutinogens, all persons in Groups II and III would be hybrid for these two elements. It would be impossible ever to find two persons crossed in Groups II or III bearing several children all in the same group. The segregating function of the germ plasm would prohibit such an event.

Impurity of the germ plasm in man is arrived at by the same means as in all animals, plants, and fowls, namely, by the association in the germ plasm in parental crosses of unlike characters.

The significance of the crossing of alternate characters was expressed by Bateson (10): "Now since the fertilized ovum or zygote, formed by the original cross, was made by the union of two germ cells or gametes bearing respectively tallness and dwarfness, both these elements entered into the composition of the original Fl (first filial generation) zygote; but if the germ cells which that zygote eventually forms are bearers of either tallness or dwarfness, there must be at some stage in the process of germ formation a separation of the two characters, or rather of the ultimate factors which cause those characters to be developed in the plants. This phenomenon, the dissociation of characters from each other in the course of the formation of the germs, we speak of as segregation, and the characters which segregate from each other are described as allelomorphic, i. e., alternative to each other in the constitution of the gametes." The quotation represents the essence of Mendelism and precludes the possibility of man being anything like a dihybrid for the agglutinins and agglutinogens of his blood stream. If such were the case cross breeding would result immediately in the segregation of the characters which entered into the formation of the dihybrid character, giving homozygous types, as well as heterozygous types. If that statement does not hold, the whole philosophy of heredity is wrong.

THE VALUE OF BREEDING PATTERNS

The patterns that have been presented in order to explain the blood group have been copied from the portion of textbooks on heredity that deals with the transmission of compound characters, and not with crosses of simple allelomorphic characters, and from cases where recessiveness and dominance were known. Furthermore, they represent the possible results of crossing of two hybrids with germ plasms that are similarly constituted.

The cross of a simple pair of allelomorphic characters requires but four squares to represent all of the possible zygote combinations. All of the data available make me believe that the blood groups behave in the germ plasm as allelomorphic characters. If the blood groups are represented by the symbols, ab, Ab, Ba, and AB, a pattern which will explain all of the phenomena which have been observed in the study of the blood by myself and others will be included in Table I. The patterns heretofore presented have been arranged to comply with data available and not in accordance with the fixed rules for making such patterns.

The prime difficulty in studying the results of crosses of heterozygotes in man is the necessity of marrying sister and brother heterozygotes, which is nearly impossible because of our social customs. The difficulty is further enhanced by the essential of proving the sister and brother heterozygous before attempting the experiment. The study is not simple. The homozygotes in each instance in the squares are designated by the subletter X, and the heterozygotes occupy all of the other squares. There are four homozygotes, or each blood group may exist as a pure type. There are twelve heterozygotes. The blood group present in the blood stream of each individual resulting from possible crosses of the gametes is represented in the lower right corner of each square, while the additional gametogenic function of the germ plasm of the individual is represented in the upper left hand corner of each square. Previous investigators have not recognized the reversibility of the evident and dormant blood groups in the heterozygote.

An analysis of Table I shows that the gametes for male and female each contain a determiner for a group, and upon union of the gametes unknown factors control which of the two determiners shall appear as a character in the blood stream of the zygote, and which will constitute the second character that is represented in the germ plasm. If the two gametes have the same constitution a homozygote will result and this individual when crossed with another like homozygote can only transmit one blood group to the offspring. If crossed with a homozygote of another group the groups of both parents will appear in the offspring. If, however, the gametes differ a heterozygote results, and if this zygote is crossed with either a homozygote or a heterozygote, and sufficient children result, the constitution of the germ plasm of the parents will be revealed by both the dormant and evident characters of the parents appearing among the offspring. The possibility of two parents in different groups bearing children in all four groups is shown in Table I and the possibility of parents in different groups having children in only three different groups is evident. The impossibility of two parents in the same group ever bearing legitimately children in more than three different groups, is pointed out in Table I. Of these three groups one must be the same as that of the parents.

MEDICOLEGAL APPLICATION OF BLOOD GROUP

The medicolegal application of the blood group is extremely limited; difficult of application, and would be, if used, frequently surrounded with danger of leading to the miscarriage of justice.

The only rule that can be formulated at this time for the use of the blood group in medicolegal affairs is that two parents in the same group can have children in only three different groups, and of these groups one must be the same as the parents. If a dispute in a family arose in which the parents were both in the same group, and they had four or more children, and the child in question happened to be in a different group from either parent, and all four of the blood groups were represented in the family, the child could be suspected of illegitimacy, but a great burden would rest upon the jury of deciding whether the mother had been caught in the first offence or whether the child in question was legitimate and another of the children illegitimate. If it could be positively proved that the child at stake was really illegitimate, how could its real father be positively proved? The parentage could not be proved by simply grouping the blood of the child and the "visiting gentleman." He might be in a different group from the child, and yet be its father. It would be necessary to prove that there was a possibility of the man being heterozygous, which would call for the grouping of his sisters and brothers, if he had any, his father and mother and his grandparents. If the man came from a small family there would be no way of proving him either homozygous or heterozygous. Even if the blood group coincided, there would still remain the possibility that another person in the same or a different group from the child was really responsible for the child.

SUMMARY

1. The blood groups are hereditary, and transmitted between generations as they appear in the blood stream. The group as a whole is the hereditary character.

2. The agglutinogens and agglutinins are neither recessive nor dominant.

3. The blood group is practically valueless for determining parentage in a medicolegal dispute.

Etiology and Treatment of Enuresis

M. K. WYLDER

Albuquerque, N. M.

No more accurate summing up of the subject of enuresis has been made than that by Davison in Abt's *System of Pediatrics,* where he says: "Much has been written but little relatively known of this condition which distresses mothers, shames children and baffles physicians." In the first place enuresis is not a disease but is only a symptom that may be caused by many conditions of widely divergent pathology and much that has been written that seems to be almost contradictory is absolutely correct for the different authors are describing different cases with entirely different causation. Let us first consider briefly some facts about the anatomy and enervation of the bladder. Elliott has recently brought out the interesting fact that the trigone muscle is not truly bladder muscle at all, but is a continuation of the muscular walls of the ureters.

ANATOMY AND ENERVATION OF BLADDER

This trigone muscle derives its nerve supply entirely from the sympathetic nerves and it opens and closes the bladder outlet; it has also been learned that there is no internal sphincter of the bladder in man, that the socalled sphincter is derived from two muscular loops, one from the circular and the other from the longitudinal coats of the bladder wall.

It is not definitely known just where sensation or the desire to urinate originates, the bladder mucosa except around the neck is not sensative. The bladder nerves seem to have a selective action, stimulation of the sacral nerves has been found to relax the bladder when it is contracted and to contract the bladder when it is at rest. Animal experimentation does not get us far because different animals have widely different urinary enervations and urinary habits and man alone is hedged in by conventions which interfere with natural impulses or instincts as to his urinary functions. Amberg quotes the experiments of Weitz and Goetz who filled the bladder with fluid under pressure and when they reached the point where the subject expressed a desire to urinate clamped the inlet tube and opened the outlet tube that was connected with a manometer. They found that in normal individuals the desire to urinate was expressed at a fairly regular pressure, while with those suffering from enuresis this desire was not expressed. Amberg, however, was unable to verify this by his own experimentation for he found that in some of his own cases of enuresis the patients expressed the desire and some did not.

The infant acquires bladder control at a variable period from six to thirty-six months, according to training and the veracity of the mother. Some mothers tell you that they have their children trained to use the vessel from six months, another not till thirty-six months, but whenever this control is acquired urination ceases to be an involuntary act and becomes voluntary. By what paths the desire to urinate is carried to the brain and from the brain back to the bladder is not known. Here is an opportunity for some real work.

Most children, except in cretins, congenital myxodemas, mongols and other types of idiocy, acquire bladder control and for some unknown cause lose it and the enuresis is developed after a variable period of more or less absolute control.

A DISCUSSION OF CAUSES

There is no clear cut idea as to the etiology of this condition; I will enumerate some of the causes as given by various authors:

Pototzky.—Considers that it is practically always a nervous symptom, and he enumerates nervous hyperexcitability, psychopathy and defects of intelligence as the three grand divisions or headings under which he classifies practically all the causes and considers it as a symptom of some neurosis.

Pisek.—Says that it is often found in an active child who plays too hard, considers it a sign of neuromuscular fatigue. He also mentions physical causes as phimosis, adenoids, hyperacid urine, but states that the principal cause is lack of control of the sphincteric centres or higher cerebral centres and states that if voluntary control is obtained or inculcated over the lower centres the case is cured.

Moss.—Quotes Atwood as stating that the detrusor muscle in children is much thicker and stronger than in adults and the sphincter is comparatively weaker and advances the idea that in sleep, when the action of the will is lost, due to this disparity of muscular strength, the urine is forced involuntarily from the bladder. He enumerates among other possible causes phimosis, paraphimosis, epispadias, hypospadias, balanitis, adherent clitoris or foreskin, pinworms, adenoids, tonsils, renal and vesical calculi, pyelitis, masturbation, vaginitis, skin disease, tuberculosis of genitourinary tract, all neurotic and psychic conditions which might produce reflex contractions of the bladder wall. He speaks of idiopathic and functional disturbances which do not reveal any specific cause and endocrine disturbances.

Kerley.—Mentions faulty development, but states that in about ninety per cent. the cause is unexplained.

Abt.—Mentions acid urine, alkaline urine, malformation of bladder and urethra, epilepsy, spina bifida, spina bifida occulta, compression, myelitis, cerebral lesions, fistula and oxyuris.

Holt.—Enumerates continued infantile condition, anything increasing irritability of the spinal centre, anything interfering with cerebral control over the centre and anything increasing irritability of the terminal filaments of the bladder nerves.

Church and Peterson.—Speak of it as a partial somnambulism and as physiological stigmata of degeneration.

White and Martin.—Call it a functional disease of unknown cause.

Porter and Carter.—Give as the principal cause improper training and the establishment of a neurotic habit.

Feer.—Mentions faulty training, nocturnal epilepsy, juvenile hysterics, considers it as an evidence of hereditary stigmata of degenerative inferiority.

Crozer Griffith.—Discusses phimosis, preputial adhesions, adherent clitoris, vulvovaginitis, balanitis, renal calculus, rectal fissure, thread worms, adenoids, foreign bodies in the nose, vesical calculus, hyperacidity of urine, hyperalkalinity of the urine, malnutrition, anemia, chorea, epilepsy, headache, neurasthenia, hysteria, improper food or clothes, fright, excitement, thyroid insufficiency, fatigue, too heavy bed covers.

This discussion of causes could be carried on *ad infinitum* as every text consulted or every author reviewed brings out some new suggestion as to causation which emphasizes the fact that there is not at the present time any very definite idea as to cause or rather there is a general idea pervading the literature that anything that disturbs us either mentally or physically may give rise to this symptom.

TREATMENT

When we come to consider treatment the same rule holds, there are as many methods given as there are causes enumerated, each showing a fair percentage of cures but not reporting their failures. Zappert has collected a list of thirty drugs all highly recommended by their advocates. Among the drugs most authors mention belladonna, and pituitrin is also popular with many of them; some suggest the use of thyroid extract, then come ergot, strychnine and nux vomica; potassium citrate and other alkalies are suggested for acid urine; bromides and hyocyamus to quiet the nerves; calomel, codliver oil, and hypophosphites, iron and arsenic as tonics and curative measures.

We find suggestions to remove tonsils, adenoids, polyps and other nasal obstructions, pull teeth, circumcise. Passing of cold urethral sounds is recommended by some as almost a specific. Hygiene and general home treatment have many advocates; cold bathing and massage, waking up at night with sufficient frequency to keep the bladder empty and establishing a dry habit. The strengthening and education of the sphincter muscles by having the child when he goes to urinate, urinate a little and stop suddenly on command and practise this stop, start, stop, start, as long as the urine lasts and by practising this several times daily there is no doubt that these muscles can be both developed and educated to do their work. Faradism and static electricity have their advocates, the necessity of rest and keeping the child free from worries and excitement is suggested by many, education of the will and hypnotic suggestion; injection of saline solution under the skin in the perineal and pubic regions, distention of the bladder by hydrostatic pressure, elevating the foot of the bed, no fluids after 4 p. m., encouragement, rewards and punishment, stimulation of the sympathetic nerves by applying pressure to any points of tenderness along the spine.

The use of a calendar with red and gold stars is recommended, the child being instructed to affix a gold star for every dry night and a red one for every wet night. This together with rest, dry supper, no fluids after 4 p. m., waking at intervals is I might say the most universally accepted system at present.

We might go on and find other suggestions but this is sufficient to show that there is no uniformity of ideas as to treatment. This fact, however, stands out that belladonna and atropine are or seem to be the standby for all or nearly all. And yet what does belladonna do and how does it act—on unstriated muscles it is a cerebral excitant; a depressant to motor nerves. Hare says it is eliminated through the kidneys almost as rapidly as it is absorbed from the stomach. If it is a sedative to unstriated muscles, does it not tend to relax the unstriated muscle of the vesical sphincter and increase the incontinence? And if it is excreted almost as soon as it is absorbed from the stomach, what local effect on the terminal nerve filaments can we expect if we get the child up frequently to empty the bladder or if he empties it involuntarily in bed?

The report of Wile and Orgel deserves special comment as they have done the most thorough piece of work that has been done or at least that has been reported. They took a class of fifty and treated them with drugs, belladonna, pituitrin, and others, and another class of fifty and treated them without drugs, and their results showed thirty-eight per cent. cures in each class but as the class under drugless treatment was forty per cent. mentally defective eliminating these mental defectives they showed forty-three per cent. cured of those of normal mentality, while those treated with atropine alone showed only thirty-five per cent. cured, and treated with pituitrin alone fifty per cent. cured. Their method with the non-medical treatment was to talk with the child, get him to express a desire to break this habit, get his cooperation and encourage him that he could, instruct the mother not to scold or punish him and to have him keep a chart with the gold and red stars and by encouraging conversation on every visit to the clinic and encouragement at home they got their results.

CONCLUSION

The points on which all recent authors agree are these: No fluids after 4 p. m., a two to three hours' rest in the afternoon; empty the bladder before retiring and again before midnight according to the time the child is found wet; use a chart with gold stars for dry nights and red ones for wet nights; encourage the child and impress on him the fact that he can get well. Is it not just possible that since cures are reported with every method of treatment that as far as drugs are concerned their effect is more psychological than medicinal? The affixing of the gold stars stimulates the subconscious control over the higher centres to greater activity and strengthens the will and the more frequently this chart is looked at, especially after it has a fair percentage of gold stars, the more beneficial the effect, for it keeps before the mind the main objective. It stimulates the desire and promotes selfconfidence and we can any of us accomplish anything we set out to do if we will only keep the main objective before us and keep striving towards it. Aside from cases of congenital malformation, neoplasms, myelitis, spina bifida, and other conditions that are of course incurable, I believe the large percentage of these cases are simply a habit condition and that with sympathy, encouragement, the proper regime and care this habit can be broken.

A complete bibliography will be included in the author's reprints.

Diminishing Number of Doctors in the Rural Districts

CHARLES L. LARKIN, M.D., F.A.C.S.
Waterbury, Conn.

During the last few years articles have been published in medical journals and discussions have occurred in medical circles concerning the diminishing number of graduates from the regular medical schools who become country doctors and general practitioners.

To remedy this it has been suggested that the premedical requirements be reduced and the period of instruction in the medical schools be shortened. This plan would undoubtedly increase the number of medical graduates but graduates of an inferior quality. So much is granted. But the remedy fails in that it presupposes that these poorly trained medical graduates will migrate to the rural communities, or stay there after locating.

The underlying thought is that the best doctors live in the cities and only the best can survive there, while the bohunks in the rural districts do not know a good physician from a poor one, and that any kind of doctor can survive in such a place.

As a matter of fact, conditions are just the reverse. In large cities there is a group of physicians and surgeons of outstanding ability who gain their eminent position by hard and conscientious work. Then there is the group of younger men of the same type striving for a place in the sun by the same route. These two groups are a credit to the medical profession. But there is another group which varies in number according to the size of the city, the larger city having the greater number. This group is made up of poorly trained, lazy, ignorant and careless medical men, fakers, quacks, and charlatans. A city the size of New York is filled with such men practising the healing arts, reaping a good financial harvest.

Why can men of the last class thrive in a large city and why do they usually starve in rural districts? Simply because in a large city there is no one to check up on their mistakes; they and their work are lost in the crowd; the pitiless light of publicity does not shine upon their ignorance and their mistakes are buried. In large cities a gift of gab, polished manner, fine offices, the right location and a small amount of ability will carry a physician a long way towards financial success as a practitioner. In the city a quack can always call in a consultant from the first two groups or he can send the patient to a hospital and thereby clear his own skirts and cover up his ignorance.

But the practice of the healing arts in a rural district or small town is quite different. A doctor may look the part and may have good offices, on the right street, but if his results are poor he is through.

A rural practitioner must be physically strong and willing to travel long distances day or night, winter or summer, over rough roads. He must be self-reliant, for there is no chance to call in a consultant, no hospital to rush to for aid, nothing but his own skill, ingenuity and nerve to take him through the worst emergencies with the eyes of relatives and often of the whole town upon every move.

In the country a patient is not a case but a personality, a friend, neighbor or acquaintance. Everyone knows everyone else. If Baby Jones cuts a tooth, it is known; if Mrs. Jones skips a menstrual period it may be a subject of remark and conjecture; if Mr. Jones has a pain or an ache it is a thing of interest and open to general discussion; not only is the name of the doctor in attendance known, but everything he says and does is remembered for future mastication and digestion. If Doctor So-and-So treats a case differently from Doctor So-and-So of the next town, and, above all, if the results are different, then the fat is in the fire.

In a factory community the compensation commissioner's office is the dispenser of medical news. If the doctor happens to get a poor result in a case that comes under the Workmen's Compensation laws then there is a general airing of the subject by the commissioner, the employer, the insurance companies, the retained lawyers and opposing doctors. The niceties of professional ethics play no part in such proceedings, the opposing doctor often taking malicious delight in damaging the reputation of his fellow practitioner. Choice tidbits find their way from such courts, supplying juicy morsels for the local newspapers.

Probably the most potent factors in undermining the rural doctor's reputation are the petty jealousies, sly remarks and innuendoes of the rival physicians themselves.

No poorly trained doctor can survive this constant gossiping, bickering, and merciless publicity, comparison and criticism. It is trying to the patience of the rural doctor, but it keeps him very alert, makes him cautious in what he says and does, and, above all, it makes him study the recent medical literature and sends him off frequently to visit the leading medical centres.

Rural people may not have the external polish of the city dweller, but they have good common sense and are frequently well informed on medical matters. They have strong likes and dislikes, know what they want and whether they are getting it. It takes a hard shelled quack to live in such a community with a record of many glaring mistakes. It is much easier to move to the city and hide in the crowd.

Rural districts are losing their doctors not because there is a general scarcity of physicians but for the following reasons:

1. They demand a higher type of physician than the average city practitioner and expect to pay less for the service.

2. A country doctor has a hard and strenuous life compared to the easy office-life in the city.

3. Country life offers very few of the refinements that are enjoyed in the city.

4. Rural districts want a local physician for only the emergency calls and these are too few in number to support an average physician. The ubiquitous

Ford makes it possible to run the chronic and subacute cases to the neighboring city. No matter how much ability the local physician may have, still a certain percentage of the people will think that the distant doctor is the best, just like the cows think the grass in the adjoining pasture is the greenest.

By lowering the medical requirements an irreparable blemish will be placed upon the medical profession without accomplishing the desired result.

If small communities need a doctor and they persist in demanding a good one, then they will have to offer suitable inducements to attract such a man. This can best be done by the community guaranteeing a certain income with a chance of making more.

Epidemiology of Scarlet Fever

DWIGHT M. LEWIS, M.D.

New Haven, Conn.

Some years ago I reported observations on the source and the manner of spread of scarlet fever, (1), (2), (3). The conclusions reached at that time were as follows:

A. For all practical purposes, the spread of the disease was due to nasal carriers. The carriers were either those of convalescence, of the missed walking case, or were those who had had the disease previously and during a later season or later years were cases of infections other than scarlet fever.

B. Whether for case or for carrier, cultures gave as satisfactory results when the morphology of a certain type of streptococcus was found as did the morphological report on the diphtheria bacillus.

Results were shown in decreased morbidity and mortality of the disease: the former was a measure of even absolute absence of return cases and of lessened secondary cases. This was brought about by the similar procedure we had learned in diphtheria. Some contact was responsible for the case infection and that one as a carrier was sought for. Carriers were also sought for irrespective of cases and were to be recognized by both clinical and bacteriological results applied during all absentee illness of school children. The measure of control of mortality was remarked, but the exact reason was not at the time appreciated.

It was of interest to me at the time that epidemiologists and some bacteriologists appreciated the facts brought out and in a number of cities took up the study of the carrier. On the other hand, a number of bacteriologists were emphatic in their opposition to the possibility of accuracy in differentiating streptococci by morphology in the absence of biological proof of characteristics. For the latter reason the statements four years later of Tunnicliffe and recently of the Dicks that a certain strain of hemolytic streptococci was biologically the organism found in, and the cause of, scarlet fever, may well bring the conditions back to my original statements. Continued field study of the past three years have borne out the facts and statements made for the first four years of observations and have yielded further material of value. An observation of former years, provocative of much discussion, was that during times of socalled grippe, scarlet fever was simulated (4).

I have followed some thousands of contacts and have yet to find that the case at onset is infectious for further cases. Where I could reach all the contacts I have always been able not only to link up the nasal or throat carrier causing the case but some other case as well. One of the most clear cut examples of the use of the culture work was given for carriers, Case VIII (1). An exact method of the control of epidemic scarlet fever in a tuberculosis sanatorium with approximately 150 patients and attendants was also related (2). The lack of infectiousness of the case at onset has been well shown during the past year. For reason of publicity of antitoxin possible only at the isolation hospital, more patients than ever have been hospitalized. In no instance have there been secondary cases referable to exposure by the patient. It has been usual to have return cases among the nonimmunes of the patient's family following the return home of the hospitalized patient. Such facts recall the older view that the most infectious period of scarlet fever was during the peeling. To substitute nasal discharge, purulent, bloody, often excoriating lip and cheek, for the peeling is to confirm the old order of observation. Recognition of this factor constitutes it the most important procedure in the prevention of the disease. During the past three years I have found that yearly, approximately ten per cent. of convalescents become such nasal carriers. I have found an average of two per cent. of the immunes in families with reported cases clinically nasal carriers. Their immunity dated from two months to seven years during the past three years, approximating a ten year period reported for Case VIII, a carrier confirmed by culture and history (1).

In all instances the carriers were convalescent from a recent respiratory infection, tonsillitis, pneumonia, or mumps for example, or from recent operative procedures such as tonsillectomy or mastoid operation. During the past three years I have not infrequently found a further essential fact. During the course of, or as has happened more frequently, during the convalescence of the patient, another member of the family, a susceptible, has developed an apparent nasal carriership. With no other history than a slight indisposition for a day or so, perhaps a slight accompanying fever, there has been neither rash nor sore throat observed as would label it a suspected or an observed case. Whether abortive case or otherwise, these apparently selfvaccinated individuals show the mucous membrane stigmata of carriership and have received as much attention in proper isolation as the other carriers mentioned.

During the past three years I have found that

accompanying varying frequencies of the disease, scarlet fever, there were varying frequencies of carriers. During and following mumps of two years ago, there was frequent replacement in the same family of later scarlet fever. An immune from scarlet fever, recently convalescent from mumps, was manifestly a nasal carrier with mucous membranes of tongue and throat suggestive of scarlet fever. The same was true following convalescence from other respiratory diseases. In the solution of these coincidences I found the apparent answer to the variations in mortality from scarlet fever. It was my experience that a recent convalescent carrier with nasal carriership always gave rise to a more severe secondary case. Yet more severe and fatal as well were the cases resulting from contact with an immune carrier convalescent from some other respiratory disease. An illustration of the usual such instance was as follows: An immune of the previous year was returned to his home from the isolation hospital convalescent from bronchopneumonia. There were five nonimmune children in the family. Within the week following, the youngest nonimmune child was sent to the hospital, a fulminant, fatal case of scarlet fever. Two succeeding severe cases followed in the older nonimmunes of the family and one neighborhood playmate of the immune child also developed scarlet fever. Following the first case I had found the immune child to be a probable nasal carrier but the warning given the family was of avail only after the further cases had developed.

The problem was again that of the earlier years. I had repeatedly sought a blood plate differentiation of streptococci to prove whether or not we were dealing with other complicating streptococci than the primary specific one found morphologically in cases and carriers. Following the recent work by Dochez and Blake, our city laboratory undertook to identify the scarlet fever streptococcus from field cultures. Reports were made from the gross findings of a blood plate and the fished colonies were studied morphologically, and controlled for hemolysis and the production of methemoglobin with a known strain of scarlet fever streptococcus. Two intercurrent facts made the study epidemiologically of much value. There was at the time a high frequency of German measles and of socalled grippe of all age groups.

Throat cultures were taken from forty-five reported cases of scarlet fever. In twenty-four instances controlled work was carried out, in ten instances the green producing streptococci reported by plate were not further controlled, in six instances report was made that streptococci were present but not identified, and in five instances no streptococci were found. Bacteriological results were complete from a total of twenty-four reported clinical cases, although the biological proof of specific agglutination was not done. The value of controlled work with a known scarlet fever streptococcus was evidenced by the early frequency with which a hemolytic staphylococcus was reported from the plate as a hemolytic streptococcus. In nine instances blood plates were reported as hemolytic streps, two of them being of the gamma type. On control work, six of the seven reported hemolytic streps were found to be nonhemolytic, and produced methemoglobin, the remaining one being hemolytic and not producing methemoglobin. Of the two reported as gamma hemolytic streps, one on controlled work proved to be the scarlet fever type and the other was nonhemolytic and produced methamoglobin. Two then of the nine reported cases were bacteriologically scarlet fever.

Clinically there was much of interest. Four of the apparently hemolytic streps from plate reports proved green producers by control were from the following clinical cases. One was the first of four cases reported within three days from a single family, the other three being removed to the hospital before cultures were obtained. All four were suggestive of grippe consequent on a convalescent case of grippe in an older child in the family, without evidence of eruption or other signs of scarlet fever. One was an adult with a quinsy, later incised. Two were in high school girls, both of whom were found to be contacts of another high school girl who in turn, as nurse maid afternoons to an infant age one, was as definitely responsible for infecting the latter, a reported case of the disease. A throat culture from this school girl carrier gave a green producing strep, nonhemolytic and producing methemoglobin on control. In four instances plate report of green producing streps was changed to hemolytic streps not producing methemoglobin on controlled work. There were then six instances of the twenty-four reported cases where bacteriologically the specific strep corresponded to a known scarlet fever strain. In seven instances plate reports of green producing streps on control proved to be nonhemolytic and producers of methemoglobin. Epidemiologically, five of these were most instructive. In one instance the case was an immune of the year previous. The physician in attendance questioned whether he was dealing with true scarlet fever and asked me to see the case. I advised him that he was not dealing with true scarlet fever, took a throat culture and advised a skin rash extinction test with a specific scarlet fever strep. On a revisit the following day a different physician was now in attendance. He had advised the family that it was a case of scarlet fever and reported it as such. The clinical course like the onset was in agreement with the culture later reported. Another instance was a typical case of German measles. Another was in an immune child of the year previous: the case now presented a septic sore throat and an atypical rash, the onset being simultaneous with scarlatiniform

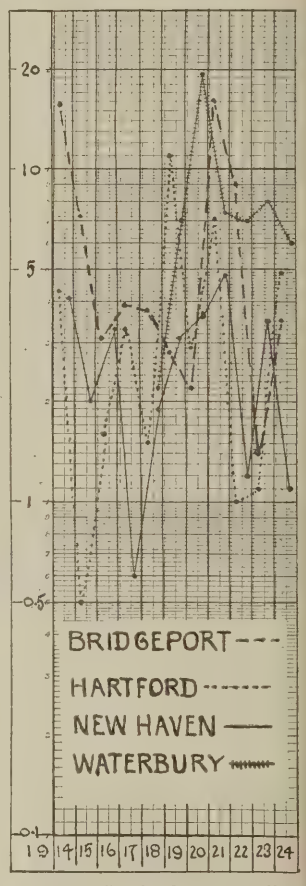

Fig. 1.—Scarlet fever mortality per 100,000, 1914 to 1924.

rashes of two younger children in the family neither having throat involvement, the course and convalescence of all three cases being that of grippe. Two further instances were very similar. From two of three children in one family, all reported cases of scarlet fever with one removed to the hospital, throat cultures were obtained. Both were green producers, nonhemolytic and producers of methemoglobin.

Cultures were taken from six evident cases of German measles. Green producing streptococci were reported from all although plate reading was not controlled.

There were six instances of referred possible cases where I sought the result of cultures as confirmatory of diagnosis that the cases were not true scarlet fever. In four instances green producers by plate and nonhemolytic, methemoglobin producing streps were reported. In one instance no differentiation of streps was reported and in the remaining instance a green producer on plate report was a hemolytic, nonmethemoglobin producer by control. In one of five instances the atypical clinical picture became by bacteriological methods a probable true case of scarlet fever.

Epidemiologically, I have ever been more concerned with carriers, convalescent or otherwise. Cultures were taken from four convalescent reported patients where nasal involvement was evident. One had been discharged a month previously without nasal involvement and three were not yet released from isolation. All four nasal cultures were reported by plate as hemolytic and on control were hemolytic and not producers of methemoglobin. Cultures were taken from twelve possible carriers. One was the throat culture of the high school girl previously mentioned. One was a throat culture of an immune of the previous year, the result being a report of fifty per cent. green producers and fifty per cent. hemolytic, the latter on control being the scarlet fever strain. The later history of the case was suggestive of the former organism being infective for the person while the latter organism was not transferred to others. In one instance the result was a hemolytic strep control positive, from a nasal carrier suspected of being the cause of three cases among his contacts. In three instances the nasal cultures proved green producers. Two of the instances were of importance. In one instance the nasal infection was field evident that he was responsible for a reported case of scarlet fever in his own family as well as in that of his cousin living remote, and the only contact of two simultaneously reported cases. Neither case proved to be scarlet fever clinically. The second instance was the most satisfactory I have yet seen. The instance was as follows:

Case.—W. K., aged five, a reported case of scarlet fever, was one of a family of four children, the youngest being a nursing infant of eight months. The patient in the reported case had an eruption lasting one day, was not only apparently well when investigated on the third day, but was without physical signs of mucous membranes involvement as well. As the patient could not be kept in bed, daily visits were made to watch developments. At the expiration of ten days there were no other signs than palpable posterior cervical glands and no further infections among the immediate family contacts. Returning at the expiration of the twenty-one days' isolation period, I found that the eight months' old infant had been seen by a specialist one week before for a sore throat. Two successive negative cultures had been taken, two doses of ten thousand diphtheria antitoxin had been given following which the specialist had informed the family that he could not save the infant's life. A medical practitioner of "years standing" was called in. He advised the family that the case was one of scarlet fever and diphtheria but that he could save the patient. At the time we saw the family, one week from onset of illness in the infant, the remaining two children had fading rashes without throat involvement, with a history of a day or two of fever, neither being confined to bed. The infant showed a bilateral marked cervical gland enlargement and was apparently septic. W. K., the patient of the original case, was now presenting an excoriating nasal discharge of ten days' duration according to the parent. The discharge yielded a green producing streptococci. At the end of a week the other two children were returned to school, the infant was admitted to the hospital where a diagnosis of bronchopneumonia was made and the carrier was isolated on the premises for a further two weeks. The infant was eventually discharged as well. In five instances nasal cultures from possible carriers were returned as negative for streptococci.

Whether then reported scaret fever cases are investigated from consideration of the morphology of streptococci in original field cultures or whether they are investigated from the viewpoint of streptococci culturally corresponding to a definite strain of hemolytic streptococci found in cases of scarlet fever and capable of producing an antitoxin for which certain statements have been made, the end result is the same, epidemiologically. Scarlet fever as a reported disease is not a clinical entity. There are years or seasons when there is a departure from the familiar type with rather characteristic symptoms and signs of onset, however mild or however severe. The departure from a public health viewpoint is one of change from low communicability to high, from one of rather definite signs to one of confusion and of doubt. There are years of low mortality and with few complications and other years of high mortality and many unusual complications. Epidemiologically, scarlet fever is simulated by German measles and by socalled grippe or better phrased, influenza.

Stripped of its complications, scarlet fever as diagnosed by its triad of signs, sore throat, eruption and temperature, is of low communicability and of low mortality. Whether complicated or simulated, the complications of otitis, of mastoids, of heart, of kidney, of joints, in fact of all pyemic manifestations are from other organisms, mainly streptococci of the green producing variety or viridans (I am not so sure but that the frequency of the socalled diplostreptococci, often overlooked, also shares equally). Such pyemic manifestations are frequent in other members of the family or contacts without the family and are as frequently assumed to have been missed cases of scarlet fever if such a later sequence occurs. A study of the results from hospitalized patients treated with the Dochez or the Dick antitoxin is in accord. Where such complications exist, they are not controlled by antitoxin treatment. Where they do not exist, anti-

toxin has seemed to have been credited with their prevention.

In nowise other fashion than with diphtheria, the epidemiology of the diseases scarlet fever included, is to recognize the bacteriology of the case and carrier, whether one of pure or mixed culture. From such findings search is to be made for the contact infector, a nasal carrier from convalescence of some recent respiratory disease. Uncomplicated specific disease whether diphtheria or scarlet fever may be controlled and the carrier of complicating organisms can be controlled from the further spread of the complicating organism producing primary infections in those immune to diptheria and scarlet fever.

If a clinical entity, the identification of scarlet fever is more than ever essential in the present day theorized control. With the Dick test for susceptibility, with specific antitoxin for aid in diagnosis by the blanching of the specific rash, and above all by the use of a specific antitoxin for both therapeutic and prophylactic use, rational use of all procedures is dependent on their use for a specific baceriological identity.

There is now accumulated sufficient clinical as well as epidemiological observations to show that an endeavor should be made to separate if possible, scarlet fever as an entity from not only its stimulators but as well, its complicators. Although the bacteriological investigation related has been limited, the sampling from the viewpoint of epidemiological factors together with the corroboration of our previous experience is more than suggestive. There is now at hand in recent literature record of case experience also corroborative. Most suggestive are those recently related by Park (5). Morphological identification of hemolytic streps from inoculated blood plates and the control of such streps with a known strain as is used for the production of specific antitoxin for hemolysis and absence of production of methemoglobin, in the absence of the demonstration of specific agglutinins would, together with the clinical rash extinction test, result in a better understanding of the various conditions of varying morbidities and mortalities of scarlet fever.

There may be added comparative statistical evidence of results of control of morbidity and mortality over an eleven year period of our work. Morbidity and mortality rates for the four large cities of the state vary little during the period, 1905-1914. For the period 1915-1924 the other three cities show similar rates for both morbidity and mortality. For this city for the period mentioned we have cut the total period mortality in two and have as well epidemic mortality rates under five per 100,000 population as compared to ten or greater for the other cities and for all four cities of the period 1905-1914. Approximately similar results have been obtained with morbidity. The illustration shows the mortality rates for the four cities mentioned.

CONCLUSION

Control of scarlet fever as diagnosed clinically is possible only when the factors that make up its variations in morbidity and mortality are elicited.

Some Observations on the Treatment of Constricture at the Neck of the Bladder

M. B. SAUNDERS, M.D.
Waco, Texas

Chronic enlargement of the prostate may be looked upon as a senile disease seldom occurring before the age of fifty, and being commonly met with after this; at a period of life as Sir B. Brodie observes, when the hair becomes grey and scanty, when atheroma begins to be deposited in the coats of the arteries, and when the arcus senilis forms on the cornea, the prostate often becomes increased in size, and may be productive of very serious effects upon the other urinary organs.

PATHOLOGY

This has been very thoroughly worked out, and I will not touch on that, only giving two illuminating illustrations and remembering the anatomical fact that the apex of the prostate is fixed by the triangular ligament.

Therapeutics offer us little relief, and the catheter while holding good for a short time, only too soon, falls by the way. Our only resort then, is surgery. The total removal of the prostate certainly is ideal, and when a success gives all we could ask. But unfortunately our clients are not test tubes for us to turn out certain reactions in the laboratory. The surgeon claims a small mortality while the practitioners on the other hand say the loss is excessive. Now what are we going to do about it? The practitioner says the mortality is too great for the operation if it can possibly be lessened, and have these old men spend the remainder of their days in peace.

Believing as I do that I have a more benign procedure that offers as good results, is the object of this paper. The old "boutonniere or buttonhole" operation as of old, but bisecting the prostate with an instrument like Dupuytren's, or Briggs' perineal lithotome, that was used when doing the median operation for stone, is to my mind the procedure of choice. It can be done at the patient's home, finished in a shorter time than the suprapubic; three to four minutes in

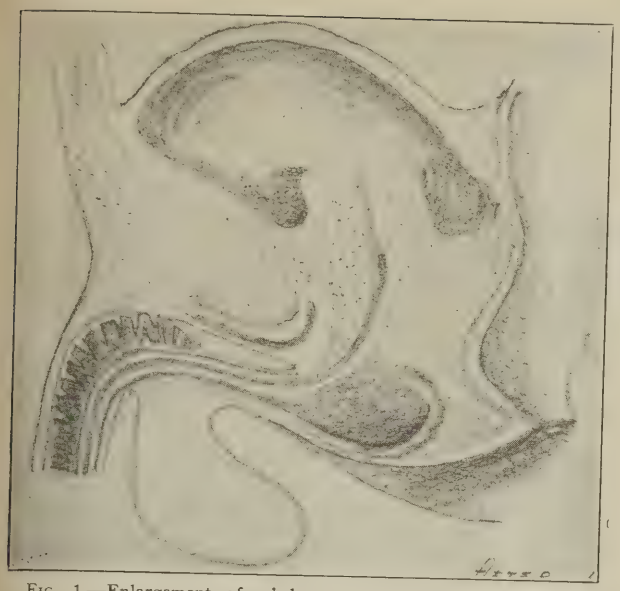

FIG. 1.—Enlargement of whole prostate, with the formation of anteprostatic and postprostatic pouches.

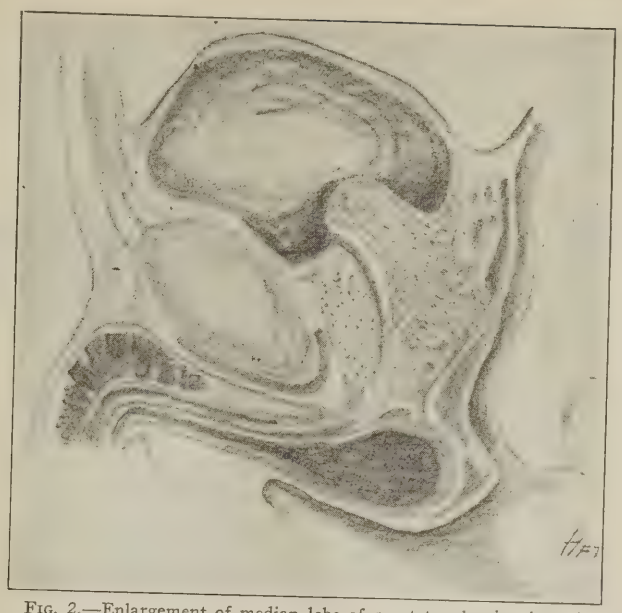

FIG. 2.—Enlargement of median lobe of prostate, showing its valve-like action.

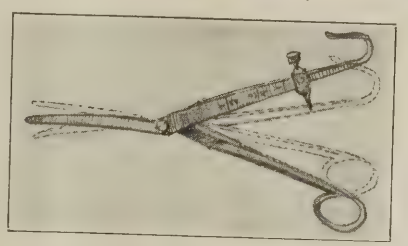
dexterous hands gives better drainage. He can be out of bed almost immediately after the recovery from the anesthesia, does not require skilled nursing, and after the first week or ten days he can look after himself, can be taken out in a car, sitting on his absorbent pad, and his recovery is certainly enhanced by these facts.

Dupuytren's method.—A crescentric incision is made half an inch in front of the anus, the two extremities which terminate on each side between the anal aperture and the tuberosities of the ischium or a little nearer the ischium, than to the anus. The membranous portion of the urethra being reached and laid open, the double lithotome cache is introduced closed into the groove of the staff, with its concavity directed upwards; when it has fairly entered the bladder the instrument is turned upon itself, so that its convexity is upward, and the blades are expanded by the grip of the right hand upon the lever; with the left hand the shaft of the instrument is sustained, and pressed somewhat firmly against the pubic arch, so as to prevent any lateral displacement and the lithotome is now slowly withdrawn. During this retrograde movement the handles must be gradually lowered between the thighs. By this method the prostatic gland is divided obliquely downwards and outwards on both sides, to any extent which may be required or which may be deemed proper; the expansion of the blades and consequently the size of the prostatic incision being regulated by a movable stop. If the operation is properly performed, the artery of the bulb, with the transverse and superficial perineal are avoided, and a larger opening is made in the prostatic portion of the urethra than by any other method. (Frank H. Hamilton, *Principles and Practices of Surgery*).



Briggs's lithotome.

For further details of the technic I use the old Briggs's lithotome, which we will have to rechristen a prostotome, following Dupuytren's method of detail. One can now easily introduce one or two fingers into the bladder, and if he sees fit can snare off any projections, and it may be an easy matter for him to peel out part of the prostate. If bleeding is of any note, gauze packed around a large drainage tube which is fastened by a stitch or two will cause it to stop and at the same time hold the cut edges apart preventing any attempt at uniting, which is hardly possible in a septic bladder.

The relief brought about by this procedure has to be seen to be realized—like magic our patient is at ease, he is able to get a good rest, the bladder is well drained and physiological rest is obtained, the first for many a day; septic absorption ceases, each drop of urine comes away as soon as passed into the bladder, and the old bladder wall lining in due time exfoliates—in many cases the prostate undergoes a remarkable process of involution—the urine returns to normal and our man is like a new being. The external wound soon closes leaving two deep channels in the prostate, and in a short time we find that he is functioning as well as if the prostate had been removed, with far less shock and less time in bed. And for this permanency over a long period, I have never seen a relapse, unless it was from malignancy.

I understand the elder Dr. Briggs of Nashville, Tennessee, treated his prostatic patients in this way some forty or fifty years ago, and Dr. J. W. Hale of Waco, Texas, who was with Dr. Briggs for some time tells me that he has operated on some one hundred and fifty prostatics, using this technic with but one death, and that he still favors this method over that of enucleation, and as to the functioning results, one gets all that can be desired.

Since writing this article Parker Syms of New York comes out with an article on Perineal Prostatectomy in the *Journal of A. M. A.* of January 23, 1926; which to my mind is the best and simplest that has as yet been devised. But, in the procedure I

have described, bisecting the prostate is, in my opinion, very much simpler, and there is not the danger of cicatricial contraction that we sometimes see when things do not go well in enucleation. However, while I have never found it necessary to enucleate, it seems to me it would be an extremely simple procedure for the finger to hull-out the gland and with such remarkable ease.

Extravasation of Urine

GEZA GREENBERG, M.D.

New York

The importance of the early recognition and treatment of urinary extravasation cannot be too strongly emphasized, for as is well known, the health of such sufferers is already sufficiently undermined by the results of a tight stricture of long duration with its consequent renal and possibly cardiac complications, and in view of the fact that such patients are usually advanced in years, many of whom being chronic alcoholics, they cannot withstand the gravity of the infection which inevitably follows imbibition of the tissues with urine. Hence recovery from this illness is in direct ratio to its early diagnosis and treatment. These patients are seldom seen in private practice, but are usually brought into the public hospital in a moribund state.

Then there is another class of cases, which in a perfect state of health meet with an accident such as falling astride a sharp object, and sustaining a rupture of the urethra with extravasation of urine. The operative results in this class of cases are far more fortunate than in the former for two reasons: first, owing to the accident they receive earlier attention; secondly, their urine is less infectious.

Many patients seek admission to a hospital with a train of symptoms outside of the urinary tract, such as gastrointestinal irritation, evening rise of temperature, marked anemia and malaise, etc., but which upon close investigation are traceable to the urinary tract as a manifestation of urosepsis, being secondary to an obstruction in the lower urinary tract and giving rise to back pressure. Such patients are not infrequently admitted to the general medical wards with urinary infiltration, or it may first develop during their stay in the hospital. Since the general symptoms eclipse the local ones, the condition is either too lightly considered as one of epididymitis by both patient and physician, or if recognized at all, is done so rather late, when red streaks of lymphatics are seen running up to the abdominal wall. When this occurs the prognosis is usually grave.

The course of the disease depends to a great extent upon the variety of extravasation, as determined by the location of the rent in the urethra in relation to the different layers of the perineal fasciæ.

When the rupture of the urethra occurs between the anterior layer of the triangular ligament and Colles's fascia, the urine may then break through Buck's fascia of the penis and imbibe the peripenile tissues with subsequent necrosis in them, or follow the course of Colles's fascia, where it communicates with the fasciae of the scrotum and abdominal wall, infiltrating the scrotal tissues first on one side then on the other, and continuing on to the abdomen. The latter is the more common course the urine takes, although it is not infrequently associated with extravasation of the peripenile tissues. Infection in this type is severe, and traveling very rapidly, leads to a fatal termination in a comparatively short time. The tissues being swollen and red are very sensitive to pressure. The temperature is that of sepsis, the pulse is rapid, and the respirations are in proportion to the temperature, and to the gravity of the infection which often invites a state of acidosis. It is usually associated with extremely marked prostration.

Then there is another variety of infiltration between the two layers of the triangular ligament, where, owing to their attachment to the pubic bones, it becomes localized for a comparatively long time. Ultimately it may find an exit in the skin of the perineum and the scrotum, forming either single or multiple fistulae, or it may break into the ischiorectal fossae and into the gluteal regions. The prognosis in this type of extravasation, due to its strict localization, is much more favorable.

Lastly, another variety of extravasation, though fortunately extremely rare, is one in which the urethra ruptures above the superior layer of the triangular ligament. Under such circumstances the urine invades the pelvic tissues, notably the space of Retzius and may even break through the peritoneum. The prognosis in this class of cases is obvious. This complication can arise only under the most extraordinary circumstances, such as, a fracture of the pelvis, a phlegmonous inflammation of the prostate, seminal vesicles, or both. Traumatism inflicted by the surgeon's knife in the course of an external urethrotomy upon an impassable stricture without a guide or by a misdirected guide following blindly and meekly the course of a false passage within the urethra, thus leading the knife outside of, and away from the urethra, may ultimately result in infiltration of the space of Retzius. A possible pelvic urinary infiltration should be borne in mind in case of an unexplainable death following a simple uncomplicated external urethrotomy, especially when associated with pain and distention in the suprapubic region in the presence of good drainage from below.

From all this, one might be led to believe that, rupture of the urethra secondary to a tight stricture is absolutely essential to the cause of extravasation of urine. That this is not invariably the rule, may be demonstrated on patients with urinary infiltration who have no difficulty in voiding, and in whose urethrae, relatively large instruments may be passed and yet their tissues are steeped in urine. Wh

seems essential, however, is an infection of some of the urethral glands whose long sinuous ducts imbedded in the corpus spongiosum are suppurating and breaking through the tissues of the urethra, thus connecting the intraurethral lumen with the periurethral tissues. Suppuration of Cowper's glands may be responsible for some unexplainable cases of extravasation.

As a matter of digression, I may add that, many strictures of the densest and most extensive variety, are caused by some abnormal glands infected with the gonococcus. These glands suppurate and break through their capsule into the meshwork of, but not through the outer sheath of the corpus spongiosum. The urine, in its descent from the bladder, dissects its way through the erectile tissue of the spongy urethra, not unlike a dissecting aneurysm, infiltrating the tissues with its salts, and causing the formation of periurethral abscesses, or a massive type of periurethritis with subsequent cicatricial contraction of the profoundest degree. This happens more commonly in the bulbous urethra. Strictures, which form suddenly after a primary attack of gonorrhea, are usually caused in this manner.

In order to demonstrate that, an impassable stricture is not necessary for extravasation of urine, I cite the following case:

Case I.—J. H., colored, aged seventy-one, was brought into the Metropolitan Hospital on May 16, 1922, in a state of coma. On examination, an enormously distended scrotum was found, which proved to be a urinary infiltration. There was no difficulty in entering the bladder with a fairly large sized catheter. Rectal examination revealed a hypertrophied prostate. His condition did not warrant any radical operation, except that of multiple incisions into the scrotum under a local anesthetic for the evacuation of the urine. He died the same day.

Another case illustrating that early intervention is conducive to prompt recovery:

Case II.—C. H., aged thirty-five, admitted to the Metropolitan Hospital on April 6, 1923, with an acute gonococcal infection. On August 7th, he developed a large scrotum infiltrated with urine. His temperature was 103.6, pulse 106, and respiration 30. He was operated on the same day. The scrotum was incised in several places; about a pint of foul smelling urine mixed with pus was liberated, and a catheter drainage instituted. On August 28th, he was up and about, but continued his treatment for gonorrhea. His trouble started from a tight stricture in the bulbomembranous urethra and an infected Cowper's gland on the left side. His age, general condition and early intervention stood him in good stead.

The following case illustrates the loss of valuable time, which unfortunately happens in a considerable number of cases:

Case III.—H. Mc., aged fifty-eight, admitted to the general medical ward on February 23, 1923, for the treatment of heart disease. Two weeks prior to his entry to the hospital, he felt a sudden pain as if something gave way in the perineum, and passed a small quantity of bloody urine. He had marked urinary frequency, almost a constant desire to void. The urinary stream was very small, amounting practically to dribbling. He entered the hospital not so much for relief of his urinary difficulty, as for that of his heart condition. Up to February 28th, he urinated spontaneously, but from that day on, he was unable to void, except a few drops at a time. Meanwhile, his difficulties increased, and his bladder became visibly distended. He was aspirated suprapubically, for attempts at urethral catheterization were futile. On March 5th he was seen by the urological service. On examination, a marked distension of the scrotum and perineum as well as that of the bladder was seen. He was operated on the same day, but succumbed on the 10th of the month to uremia. He evidently did not think it of sufficient importance at the time he noted blood for the first time to invoke medical aid, thinking as a good many other ignorant patients do when asked about any urinary difficulties that, they have none, intimating, as is a favorite expression of theirs, that their kidneys work well. This often leads the inexperienced physician astray, and he does not suspect the grave situation until it is too late.

That all cases of extravasation are not hopeless even when the urine has broken through the tissues and caused necrosis in them, is demonstrated by the following case:

Case IV.—T. H., aged fifty-three, admitted to the tuberculous ward on March 19, 1923. During his stay there, he developed an ischiorectal abscess, for which he was operated. On June 9th, he had acute retention for which he was catheterized that day and the following three days. On June 12th, his penis and scrotum became swollen; on June 15th, the urine was seeping through the scrotal skin, which became black and purple in places. On June 18th, he was transferred to the urological service, where he was operated under local anesthesia. He made an uneventful recovery and was discharged August 13, 1923.

Case V.—W. K., aged fifty, admitted February 10, 1922, with retention of urine and extravasation, the scrotum reaching the size of a grape fruit, and necrotic in places; on operation an impassable stricture was found. In order to expedite matters, since the patient was in a moribund state, a cystotomy was performed and the scrotum drained. The whole operation lasted five minutes. The patient developed pulmonary edema the same day and died the next. His extravasation was probably of a few days standing. Both his age and duration of illness militated against his recovery.

The oldest patient to be operated on for extravasation was A. O., aged eighty-nine, admitted October 20, 1920, with swelling due to urinary extravasation of penis, scrotum, and suprapubic region. He had absolute retention for fifteen days prior to his entry into the hospital. He had an impassable stricture. Under an anesthetic, the urethra was entered by a catheter under great difficulty, left in for drainage, and multiple incisions made into the extravasated area. On November 2nd, he became comatose and died of uremia and cardiac decompensation.

Of all the patients operated at the Metropolitan Hospital since 1917 ranged from the ages of thirty-five the youngest, to eighty-nine, the oldest. While I could cite quite a number of other cases, meeting with the same tragic end, I shall mention just two more cases to illustrate a complete closure of the urethra from an extraneous cause:

One of them, occurring at the Metropolitan Hospital, on account of its extreme rarity, and not having read of a similar case in literature, was indelibly impressed on my mind, so that with the exception of the date of occurrence, I can cite with precision and accuracy the following case from memory:

CASE VI.—A man fifty-eight years old, just recovered from a herniotomy, was brought to the urological service with acute retention of urine. On examination, the catheter was arrested at the junction of the bulbomembranous urethra, and on its withdrawal, liquid feces came away with it. The scrotum and perineum were enormously distended with urine and feces. The examination of the rectum, while the patient was under the anesthetic, revealed a large nodular mass surrounding the rectum and practically shutting off the exit to the solid intestinal contents. Owing to the close proximity of the rectum to the membranous urethra, in fact, being intimately connected with it by the common attachment of the rectourethral muscle to both, the tumor broke through the rectal wall into the bulbous urethra at the junction of the bulb with the external sphincter and allowed the escape of feces into the surrounding tissues. The urine likewise descending from the bladder through the membranous urethra met with a similar fate; its further advance through the urethra having been hindered on account of closure of the bulbous urethra, and seeking the place of least resistance, it broke through the bulb and escaped into the perineal and scrotal tissues. The operation consisted in establishing a permanent urinary suprapubic fistula, forever diverting the urinary stream from its normal channel, and making multiple incisions into the extravasated tissues and draining them thoroughly. The general surgical service was called in to establish a permanent anal fistula, but, owing to his poor condition, they applied palliative measures of dilating the stricture and passing a large rectal tube to divert the fecal stream. Contrary to my expectations, however, he hold on tenaciously to life for a period of five months, at the end of which time, he died of general cachexia incidental to his carcinoma.

While citing but a few cases, space not permitting more, I believe that I have emphasized and demonstrated sufficiently the seriousness of the disease, and the importance of early diagnosis. The sudden appearance of a bilateral swelling of the scrotum in one who has apparently been in perfect health, but who gives a history of having had one or more attacks of gonorrhea with possibly some frequency and dysuria, and the swelling increasing in size and extent, associated or not with a similar swelling of the penis, and a swelling in the suprapubic region due to a distended bladder, with complete or incomplete urinary retention, leads to but one diagnosis—extravasation—add to this the characteristic edema of the scrotum, lymphangitis, fever, with all its symptoms, and above all, marked prostration, the diagnosis is beyond the peradventure of a doubt.

Ordinarily the following conditions must be differentiated from it. Acute bilateral epididymoorchitis, acute hydrocele, hernia, and for the sake of completeness, though this question rarely presents itself, elephantiasis due to filaria hominis. Occasionally after a bilateral bubonectomy of the inguinal glands a marked edema of the scrotum develops, but should never interfere seriously with the proper diagnosis. The history of the case as to onset and duration, pain and tenderness—the latter two symptoms, not being conspicuous in extravasation, except in the last stages when infection has been superadded to the extravasation—with absence of prostration and some of the other symptoms and physical signs enumerated in connection with urinary infiltration, should differentiate acute inflammation of the testes and epididymes from extravasation of urine. This is really the most common illness confused with that of urinary extravasation.

The others can be easily differentiated by the history, onset, duration and absence of symptoms of extravasation.

The prognosis depends on the duration of the extravasation, the age of the patient and the primary cause. Complete urinary suppression with impending uremic symptoms usually usher in the end.

The indications for treatment are drainage of the urine from the tissues, restitution of the normal direction of the urinary stream, in other words, away from the tissues which have been waterlogged by urine; combatting the infection, and supportive measures for the extreme prostration caused by the toxemia and probable acidosis.

Since the patient as a rule is in extremis, it is requisite that he be given due consideration for that, and that the operation be performed as expeditiously as is consistent with his safety. If the stricture cannot be entered without a great loss of time and with a great deal of dissection of the tissues, thereby enhancing the spreading of infection, I believe the safest procedure is to open the bladder, drain it and the space of Retzius, which I think is more often infected than suspected, and extensive multiple incisions into the extravasated areas be made. If the stricture can be entered with a catheter, then the best surgical judgment is to fasten the catheter into the bladder, incise the tissues, and wait for satisfactory convalescence to complete the urethrotomy. To combat infection, and shock, subpectoral infections of normal saline, rectal infusions of five per cent. glucose and five per cent. sodium bicarbonate solutions should be given by the Murphy method every four hours. In extreme cases blood transfusions may be resorted to.

120 EAST THIRTY-FOURTH STREET.

Case VII will appear in the author's reprints.

Energy Expenditure of Women During Horizontal Walking at Different Speeds.—H. Monmouth Smith and Dortha Bailey Doolittle determined the energy expenditure of women during horizontal walking, and found that it is of the same degree as that of men when walking at moderate speeds this value being from 0.450 to 0.550 calorie per horizontal kilogrammetre. The energy expenditure per horizontal kilogrammetre is greater at an abnormally slow speed than at moderate speeds. The menstrual period appears to be without definite influence on the standing metabolism.—*Journal of Biological Chemistry,* October, 1925.

Practical Therapeutics

TREATMENT OF HYPERTONUS AND ARTERIOSCLEROSIS

S. E. Witt, M.D.
New York

Animasa is an organic preparation which, when administered by mouth, reduces normal as well as hypertonic blood pressure regardless of its origin. It is derived from intima and media of young sound fat cattle, fetal extract and by products of erythrocytes. Animasa, which abounds in protein substances, differs from the vascular preparation of Heilner as well as his cartilaginous extract sanarthrit. Heilner's preparations are protein free.

The preparation is supplied in the form of a pellet, which is sugar coated. Professor Griesbach, of the University of Giessen, Germany, made the following test: Samples of the somewhat hygroscopic contents of the pellets were reduced to ashes, after having been dried in a vacuum at 100° C. until they had attained a constant weight. The results from the three samples were as follows: First sample, 5,537 per cent.; second sample, 5,184 per cent.; third sample, 6,263 per cent. ashes. Tests for phosphoric acid negative. CO_2 and F. could be pointed out. Spectroscopic tests showed only the natrium line. Suspected calcium was not found either by precipitation or by spectral analysis. A watery infusion of the original substance gave positive biuret reaction. The kind of proteins has not been definitely determined. Analysis of the elements made with two samples gave the following results: First sample: C, 50.23 per cent.; H, 6,763 per cent.; N, 14.74 per cent.; S, 0.978 per cent. Second sample: C, 49.75 per cent.; H, 6,609 per cent.; N, 14.43 per cent.; S, .901 per cent. The nitrogen contents were controlled by two micro-kjeldahl determinations. One showed 14.29 per cent., the other 14.33 per cent. N. The average of the four nitrogen tests showed 14.45 per cent. This would correspond approximately to an amount of protein substances of 90.3 per cent.

For the last several years this preparation has been used successfully in various clinics abroad for the treatment of hypertonus and arteriosclerosis, in certain forms of migraine, and also in spasmophilia. Various investigators assert that it brings about an improvement in the arterial wall in arteriosclerosis. Dr. F. Jacoby, of Magdeburg, Germany, has used animasa in old arteriosclerotic luetics with very good results, he uses the preparation in combination with the antiluetic treatments. Dr. Migeod, physician in charge, Bad Tolz, Germany, has been using this remedy in both mild and severe cases of arteriosclerosis with good results. He says, "From my own experience with animasa I consider it a most suitable remedy for either the incipient or the fully developed diseases of the arterial walls. It counteracts poisonous elements in the blood circulation and restores zest in life and work as well as insures a comfortable old age, in fact under certain conditions even means prolongation of life."

Eminent research workers have shown that an intestinal wall, although scarcely changed in a pathological way, may occasionally permit the passage of albumins that are foreign to the organism. These foreign albumins (Fremde eiweissstoffe) may give rise to toxic irritation. Urticaria caused by ingestion of some food stuffs and other phenomena of alimentary intoxication, likewise the idiosyncrasies toward different foods, are clear signs of toxic protein effect caused by the partaking of them by the oral route.

Widal, Funck, and many others state that very similar processes take place during the rise of certain metabolic diseases. Pfieffer found that products of albumin decomposition could raise or lower the blood pressure in proportion to the amount of the dose administered and in accordance with albumin decomposition. Watelet and his coworkers succeeded in aborting an asthma, which was caused by anaphylaxis by administering a small antianaphylactic dose of peptone.

Funck and Hülse have demonstrated by the Abderhalden method that products of protein decomposition are to be found in the sera of patients suffering from arteriosclerosis. They were able to show further that these foreign products of protein decomposition will pass through the normal intestinal wall unchanged. These products circulating in the blood led, as was proved, to a permanent vasoconstricting effect.

Kuczynski, Ortloph, Volhardt and many others have shown that this vascular spasm led to a change in the intima of the arteries and subsequent calcification.

According to many authors, the majority of arteriosclerotic affections are due to the foreign products of protein decomposition circulating in the blood. A number of investigators have succeeded in inhibiting the effect of these products of protein decomposition by oral administration of other decomposed proteins (eiweiss abbaustoffe). Watelet and Widal had great success in thus treating angiospasmodic affections. Brack obtained good results in affections of the liver.

Wirtz succeeded in neutralizing or inhibiting the action of the decomposed proteins found in the circulation of arteriosclerotics with products of decomposed proteins obtained by a special process, which passes through the intestinal wall unchanged and brings about a lowering of blood pressure. He combined this blood pressure reducing substance with the extract of intima and media of arteries, which is believed to restore and strengthen the selfprotecting powers of intima and media. In the diseased arterial walls it is supposed to bring about an arrest and possibly a repair of the arteriosclerotic process.

Recently, Hirsch, of Jena, confirmed the effect of such a sensitization reaction and the effect of these hormonelike substances, which pass through the intestinal wall unchanged.

If the hypertension or arteriosclerosis is not due to factors described above, namely, the effect of the foreign proteins circulating in the blood but due to

some other causes, then the second mode of action of animasa vis: the organic specific influence on the diseased arterial walls shows itself in the evident improvement of arteriosclerotic ailments, as evidence by reports of patients as well as clinicians.

Heilner, of the University of Munich, succeeded in preparing an extract of intima and media, which, injected intravenously, has a beneficial effect on the diseased vessel walls in arteriosclerosis. This treatment, however, has frequent dangerous reactions that limit its use.

For the last several months, I have been using animasa in thirty-nine cases of hypertonus and arteriosclerosis, with successful results in each instance. Below are the histories of several typical cases:

Case I. Mrs. I. T., sixty years old; three children in good health, no miscarriages, husband in good health. A diagnosis of arteriosclerosis and hypertonus had been made. I first saw her on July 29, 1925 when she complained of precordial pains, frequent choking sensation, palpitation of the heart, shortness of breath on exertion, terrifying dreams and fatigability. Blood pressure systolic 212, diastolic 162. She was put on tablets of animasa.

On August 6th, her blood pressure was 188/140 and her condition was much improved. On September 28th, blood pressure was 180/120 and condition same as on August 6th. October 13th, blood pressure was 182/110; condition unchanged. October 26th, her blood pressure was 180/116 and no tablets had been taken since October 13th.

Case II. H. A. D., male, pharmacist, widower, for the last several months had been complaining of steady pains in the right temporal region with frequent shortness of breath, dizziness and insomnia.

Diagnosis; arteriosclerosis and hypertonus. On April 7, 1925, the patient's blood pressure was 196/158. He was given one animasa tablet three times a day. On April 19th, his blood pressure was 162/130, all symptoms had disappeared, and he was feeling fine. On June 11th, blood pressure was 158/130, and general condition was unchanged. On July 21st, his blood pressure was 162/130; no tablets had been given for a week, and his condition was unchanged. On September 21st, his blood pressure was 156/120 and he was in excellent condition.

Case III. B. A. S., female, widow, seventy-three years old, had been confined to bed for a number of months. She complained of severe headaches, dizziness, palpitation of the heart, shortness of breath, indigestion, insomnia and was afraid to leave her bed. Her teeth were in a bad condition and they were subsequently extracted.

Diagnosis; arteriosclerosis and hypertonus. February 17, 1925: blood pressure 240/130; she was put on two tablets of animasa three times a day. March 2, 1925, blood pressure 165/88; condition much improved. March 23, blood pressure 160/98; all symptoms disappeared. May 14, 1925, blood pressure 166/92; no tablets for a month. June 17, 1925, blood pressure 158/100; no tablets for three weeks. July 23, 1925, blood pressure 154/110; tablets for one week. September 14, 1925, blood pressure 168/120; no tablets taken. November 6, 1925, blood pressure 162/100; no tablets taken; patient in fine condition.

Case IV. A. W., male, widower, fifty-six years old, complained of headaches, dizziness and ringing in the ears. Diagnosis, arteriosclerosis and hypertonus. July 27, 1925, blood pressure 206/160; put on two tablets three times a day. August 3, 1925, blood pressure 152/116; patient said that he felt much better. September 5, 1925, blood pressure 148/116; patient said he felt fine except for an occasional ringing in the ear. September 29, 1925, blood pressure 158/116; no tablets. October 15, 1925, blood pressure 138/110; no tablets. October 28, 1925, blood pressure 142/98; no tablets.

Case V. O. M., male, sixty-five years old, elevator man; complained of headaches, dizziness, palpitation of the heart, shortness of breath on exertion, feeling of numbness in both upper extremities, especially on the right side.

Diagnosis, arteriosclerosis and hypertonus. May 7, 1925, blood pressure 204/136; put on two tablets three times a day. June 15, 1925, blood pressure 176/132; condition much improved. July 7, 1925, blood pressure 172/128; no tablets taken. August 24, 1925, blood pressure 170/112; condition much improved.

Case VI. L. A., female, forty-seven years old, housewife, had been complaining for the past several years of headaches, dizziness, blurring of vision, insomnia, shortness of breath on exertion, indigestion and frequent urination. She had been treated by numerous physicians with little or no relief.

Diagnosis, hypertonus. March 18, 1925, blood pressure 172/138; patient given two tablets three times a day. March 26, 1925, blood pressure 150/110; patient much improved. May 6, 1925, blood pressure 110/70; patient was feeling fine, tablets were discontinued. July 10, 1925, blood pressure 122/90; patient was in fine condition.

COMMENT

The results obtained from the use of animasa in thirty-nine cases of hypertonus and arteriosclerosis have been beyond my expectation. It is administered by mouth and there is no reaction following its intake.

Notes on the Etiology of Eczema*

FRANK C. COMBES, JR., M.D.

New York, N. Y.

Eczema, as a dermatological entity, is first mentioned, according to Hebra, by Aetius of Amida (A. D. 543). For many centuries it comprised the most of dermatology, and was considered due to a lack of equilibrium between the body humors. Willan, in the latter eighteenth century, first described the disease with any accuracy; but limited it to the moist vesicular forms, including all types of acute dermatitis. Other observers added to the multiformity of the disease, particularly Erasmus Wilson, who included all dry forms of eczema; until about half a century ago, it comprised nearly sixty per cent. of cutaneous conditions requiring treatment. Beginning with Unna, the pendulum began to swing in the opposite direction, until today eczema appears as a diagnosis in less than twenty per cent. of cases. The reason for this apparent decrease is the result of an elimination of various types of socalled eczema, which have been reclassified under a definite etiology, and now appear as separate and distinct disease entities.

In view of the meagerness of our knowledge regarding the causation of eczema, I think the preferable way to consider the subject is by a process of exclusion. Naturally, the first cases to exclude are those now considered noneczematous in nature and of a definite etiology and pathology. Following that, we will consider the many alleged causes of eczema and exclude them as predisposing and contributory factors, rather than real exciting agents, leaving the true nature of the disease *pro nunc* unknown.

The diseases formerly identified as eczema, and which are now recognized as separate conditions may be divided into two classes: first, those in which the etiological factor is bacterial or mycotic; secondly, those which are dependent on irritation alone for their production, are preceded by itching, never vesiculate, and do not necessarily follow socalled eczema.

Socalled Eczema Due to Parasites

1. seborrheic dermatitis

One of the first diseases to be eliminated from the general classification of eczema was seborrheic dermatitis. This was described and defined by Unna in 1887 (1). His original description included most of the socalled eczemas occurring in "seborrheal regions," and in addition pityriasis capitas (Van Harlingen), seborrhea sicca, seborrhea corporis (Duhring), lichen circumscriptus (Willan and Bateman), lichen annulatus (Wilson), and lichen gyratus (Biett and Cazanave), making it probably the most common of all skin diseases.

From scales of seborrheic dermatitis have been isolated, two organisms: The *flaschenbacillus* of Unna (spore of Mallassez), which resembles a yeast rather than a bacterium, and the Micrococcus cutis communis of Sabouraud, which is probably a staphylococcus.

Although Unna's original views have not gained general acceptance, the disease is recognized as infectious in nature and dependent upon parasitic agents for its production.

2. dermatitis infectiosa eczematoides

This disease was first described by Engman in 1902 (2), who pointed out that it was not eczema in the then accepted sense, bearing an intermediary position, with some characteristics of impetigo, although not identical with socalled impetiginous eczema. It is definitely infectious in nature, the staphylococcus aureus and albus being the causative factors. These can be isolated and experimental autoinoculation successfully performed, thus fulfilling Koch's postulates. The disease attacks the exposed surfaces of the skin, frequently gives a history of trauma or infection, and yields to ordinary antiseptic and germicidal applications.

3. epidermophytosis

The definition of epidermophytosis as a distinct clinical entity has been the greatest step in advance toward classifying our knowledge of eczema during the last quarter century. Although the definition of the parasitic nature of seborrheic dermatitis by Unna added much to our knowledge of the disease, it has not received the general acceptance that has been accorded epidermophytosis. Much of the work in its identification was done by Sabouraud, Castellani, Chalmers, Ormsby and Mitchell. It includes the

*From the dermatological department of the University and Bellevue Hospital Medical College.

eczema marginatum of Hebra; also many cases of chronic eczema of the palms and soles, and some cases of general patchy eczema. The clinical characteristics are not unlike eczema, as we are acquainted with it, except that it is more sharply defined, chronic in nature, and does not respond readily to ordinary stimulating applications. In the scales and deep seated pustules may be found a tinea, usually the Epidermophyton cruris (Castellani).

Socalled Eczemas Due to Irritation

1. neurodermitis

This condition of the skin, frequently diagnosed as eczema, has been allotted a variety of names, the more familiar being lichen simplex chronicus (Vidal), lichen chronicus circumscriptus (Willan and Bateman), prurigo circumscriptum, and pruritus with lichenification. The nosology and etiology of the disease (if it is a disease sui generis) are obscure and confusing. The majority of the French school of dermatologists consider neurodermite as a distinct disease, and see no reason for the apparent confusion, regarding its classification. Brocq has defined two types of lesion (3), neurodermitis circumscriptus and neurodermitis diffusus. Dermatologists, other than the French, interpret neurodermitis as a manifestation of prurigo or eczema or lichen. The clinical progress of the disease differs so decidedly from these three conditions that there should be no difficulty in distinction. Neurodermitis is not dependent on any irritation of external nature for its production, the lesions are preceded by itching, and never vesiculate.

2. fox-fordyce disease

This dermatosis, also known as "a chronic papular dermatitis of the axilla," was described by Fordyce (4) as regards its histological aspects, and by G. H. Fox (4) as regards its clinical features. Fox's tentative diagnosis was a chronic lichenoid eczema; but on its lack of response to stimulating therapeutic measures a biopsy was done, revealing the condition to be a hyperkeratosis, extending into the sweat glands and hair follicles.

The disease is usually limited to the axillæ and pubes, is papular in character, occasionally associated with fine fissures due to a hyperkeratosis and acanthosis of the epidermis, and is very pruritic. In a later paper Fordyce (5) offers as his opinion that the disease is identical with Brocq's neurodermite, and is due primarily to irritation which is probably toxic in origin.

Having eliminated a large number of socalled eczemas, we are now prepared to consider those factors instrumental in production of eczema. Whether eczema really exists as a clinical entity, distinct from dermatitis, is an open question, aside from the purpose of this paper.

Etiologically, the various conditions predisposing to eczema can be divided into internal and external. I call them conditions, because they cannot be called causes, since the latter invariably result in a definite effect. Such is not the case, since the apparent cause may exist repeatedly without the same effect, and vice versa.

3. eczema following external irritants

This type of eczema may be called a developmental or evolutionary eczema, since it succeeds on a prior existent dermatosis. Following I have enumerated the various agents which frequently give rise to an erythema, sometimes resulting in a persistent eczema. Along with each irritant I have enumerated the number of cases which have developed eczematous lesions. The percentages are of necessity high since only when the lesions are recalcitrant does the patient apply for treatment.

			Percentage
TRAUMATIC:			
a. scabies, pediculosis	43	6	14
b. garters, rings, trusses, belts, etc	16	2	12
PLANT TOXINS	56	2	4
CHEMICALS:			
a. soap	..	..	..
b. hair dye	7	2	28
c. clothing dyes	1	0	0
d. fur dyes	9	3	33
e. occupational irritants	102	19	19
f. actinic rays	27	0	0
CIRCULATORY DISTURBANCES:			
a. frost bite	7	1	14
b. varicosities	22	16	73

That eczema frequently develops as a sequel to scabies and pediculosis is a well known fact. That it sometimes persists indefinitely after the apparent cause is removed is also common knowledge. However, it will be noted that only fourteen per cent. of patients affected developed eczematous lesions from this cause.

The local application of certain drugs and chemicals is irritating to some skins, while innocuous to others. In some industries chemical irritants give rise to a mild dermatitis in some workers, and in others a deep vesiculation, resulting in an eczema of many months' duration. On the contrary, many workers are exposed without any deleterious effects whatsoever. The following case is illustrative:

Case.—A. C., a woman, thirty-two years of age. Previous history of no consequence. About February 1, 1924, she applied one of the commonly advertised analgesic salves to her chest and neck for a bronchitis. She repeated this several times during the day, and later noticed a reddening and burning of the skin. This gradually spread in spite of soothing applications, vesiculated, and became very pruritic. In the course of a month it had extended to her face and shoulders, and down as far as her waist line. I saw her about a month later and she had a well developed eczema covering the above mentioned regions. Inquiry of the manufacturer revealed that of millions of sales, he had had only six complaints in which a severe dermatitis had followed the use of the remedy. In conclusion, we may say that in view of these facts the external irritant acted in this case merely as an excitant.

Of the many people using paraphenylenediamine hair dye, in only a few does a true eczema develop. I recall only two or three cases that I have seen in which the mild dermatitis produced did not clear up quickly. However, in some cases a persistent eczema does develop, which although amenable to treatment shows a tendency to relapse, long after the dye has been washed from the hair.

The development of eczema as the result of irritation of various dyes used in the manufacture of clothing, hats, furs, etc., is familiar to us all. However, Roxburgh (6) points out that but a small percentage of dyed fur wearers suffer from dermatitis, and a still smaller percentage suffer from eczema. Also, the length of time for which the furs are worn before the appearance of the rash varies from two to

twenty weeks. He believes the condition may be akin to a developed sensitivity.

The forms of eczema due to varicose veins and associated with dry skins deserve only passing mention.

H. Jaeger (7) reports a number of experiments to ascertain whether eczematous patients react differently from those of normal skin to external agents. One hundred and forty patients with healthy skins were used and seventy-seven with eczematous lesions of different types. They were all subjected to the same routine. Only four per cent. of the skins of normal people showed any reaction to the external agents used. On the other hand, in fifty-one per cent. of the eczematous patients new lesions developed on the irritated area indistinguishable from acute vesicular eczema. He concluded that this susceptibility was due to a "tissue idiosyncrasy," and not to a humeral defect or internal dysfunction.

In conclusion, we can say that external irritation alone is not a sufficient cause for eczema. That of the number of persons exposed to the various irritants mentioned as the sole causative factors, only a few exhibited the disease. It is necessary that some underlying pathology exist that produces what we are pleased to call a susceptibility or eczematous diathesis.

Alleged Internal Causes of Eczema

1. digestive disturbances

It is true that in many patients exhibiting eczematous lesions there occur digestive disturbances. In the majority of cases I have found a hyperacidity of the gastric secretion and a hypotonus of the bowel accompanied by flatulence and indicanuria. However, we find hyperacidity in many other dermatoses and in patients exhibiting no dermatological lesions whatsoever. Furthermore, patients may have eczema for years without the digestive apparatus furnishing any perceptible symptom to the patient.

According to Ehrman, the mechanism of eczema may be explained by the hypothetical absorption in the gastrointestinal tract of relatively large protein molecules which are irritating to the skin papillæ and result in simple exudation. Local toxemia results in sensitization, and a slight external stimulus is then all that is necessary to produce a typical eruption of eczema. This explanation is rather fanciful and bears little clinical confirmation. Urbach (8), in a series of 182 eczematous patients, demonstrated a majority with hypoacidity. This would tend to substantiate a deficiency in protein digestion. However, I am of the opinion that gastric hyperacidity is far more common.

In conclusion, we can say that correction of the gastric disturbances only rarely results in curing the eczema, and it therefore cannot be considered as the etiological factor.

2. disturbed metabolic ratio

Perhaps no other cause has been held responsible for eczema so frequently as a disturbed metabolic ratio, that is, an ingestion of an excess of fats, carbohydrates or proteins.

As regards the fat and carbohydrate metabolism, there is no evidence that they are particularly involved other than in infants, and then only as a contributory factor. Pulay (9) reported a hyperglycemia in a large number of cases which he considered increased the sensitivity of the skin to light. McGlasson (10), in an exhaustive paper on hyperglycemia, considered it only as a contributory factor in some eczemas, and did not find it present with sufficient regularity to consider it of great etiological import. It is true that lesions occur quite frequently in diabetics; but on the contrary many patients with a high blood sugar and glycosuria never present a dermatosis of any character whatsoever.

In reference to the protein metabolism, a large percentage of eczematous patients exhibit a hyperuricemia. This is particularly true of those between forty and sixty years of age. This is quite normal for patients at this time of life. Severe eczemas in children have also shown a slight increase in uric acid. I am of the opinion that this is the result of the eczema, due to absorption of the protein exudate. Similar increases are occasionally noted in absorption of pleuritic effusions and transudates. On the other hand certain eczemas are favorably influenced by treatment directed toward the relief of a uricemia.

As regards the metabolism of the inorganic salts, I know nothing other than that there seems to be no disturbance of any constancy of the chloride, sulphate, and phosphate ratio in the disease.

In conclusion, we may say that as regards the metabolic ratio in eczema, there are no changes that occur with any regularity. However, changes brought about by other internal diseases which may vary the blood chemistry may have such an effect upon the skin as to favor the development of the disease.

3. food allergy

An attempt has been made to link eczema with urticaria as a manifestation of food sensitization. This sensitivity is quite common as the apparent cause in infants, but less so in adults. In infants I have found egg to be the most common offending protein. Wheat is also the cause in a large number of cases. Quite often we find a combination of two or more proteins causing the sensitivity.

The following case is illustrative of evident sensitization:

Case II.—C. H., aged two and a half years, had suffered since the age of four months with eczema, which, though at no time very severe, was annoying and persistent, especially over the flexures of the joints, buttocks and face. Periodically, the child would be thrown into an asthmatic attack, particularly when it had contracted a cold, the attacks lasting from fifteen minutes to several hours. Concomitant with these attacks there was an exacerbation of the eczema. In March, 1922, cutaneous tests showed the child sensitive to egg and potato. Withdrawal of these articles of food resulted in complete recovery. I saw the child a year later and it was in perfect health. Whether it is able to partake of these foods at the present time I do not know.

Abramowitz (11) recently reported a case due to the protein emanation of chicken feathers, which cleared up promptly on desensitization.

The manner in which these proteins act is still problematical. It is probable that they effect an irritation of the vagotonic nerves, producing circumscribed areas of capillary dilatation producing pruritus. The trauma resulting from the scratching of the lesions and a local anaphylaxis may be sufficient to

produce the eczema. Most of these eczemas resulting from protein hypersusceptibility are dry, papular and do not vesiculate. Many of them may be classified as neurodermitis. Wise and Ramirez (12), in a recent paper reported several cases of neurodermitis apparently caused by ingested proteins.

Bacterial proteins have been held responsible for eczema in the same manner. I have never had a patient give a positive reaction to a bacterial protein who improved upon vaccination with the same.

In conclusion, we may say that eczema appears as one of the manifestations of protein hypersusceptibility; that it appears as a developmental or evolutionary manifestation of cutaneous irritability; that it occurs in relatively few cases, and therefore cannot be considered to hold the same relationship to allergy that is occupied by urticaria and other manifestations of anaphylaxis.

THE ENDOCRINE GLANDS

In consideration of the relation of the endocrine glands to eczema we are necessarily working on entirely empiric grounds. We are all familiar with the effects of lactation, pregnancy, the climacteric and puberty upon cutaneous diseases. I consider this effect to be brought about by certain variations in the equilibrium normally maintained between the vagotonic and sympatheticotonic nervous systems. The impulses proceeding from their opposing fibres control the vital processes of the body. They are responsible for the secretory and motor abnormalities of the gastrointestinal tract, for the manifestations of anaphylaxis, for disturbances in the metabolic ratio evidenced through the blood, and other pathological conditions advanced as etiological factors in the production of eczema.

However, the endocrine glands constitute only one factor in maintaining this balance of nerve control, and therefore can be considered only as a contributory cause of the disease.

CONCLUSIONS

1. External irritation alone is not a sufficient cause for eczema.
2. In those cases in which external irritation is the sole apparent cause, a parasite is probably present, and we are dealing with a noneczematous lesion.
3. The most reasonable cause for the disease lies in a lack of balance in the autonomic nervous system, associated usually with an external exciting factor.
4. The internal treatment of the disease should be along lines tending to restore this balance to normal, rather than by measures directed toward the correction of the various manifestations of vagotonia and sympatheticotonia.

The Endogenic Nature of Some Skin Diseases*

Critic of Bloch's Review of Skin and Metabolism

GUSTAV SINGER, M.D.
Vienna, Austria

The old humoral theory of the origin of skin diseases that cover the entire body has been displaced by the advance of cellular pathology. Only in the last decade have the results of the investigation on immunity led to an appreciation of the origin of hypersensitiveness, the allergy and the sensitization of the skin, and also showed the similarity of these affections with the skin symptoms of serum disease and anaphylactic shock.

The complex of the skin diseases, which can be traced to a hematogenic influence of certain noxa, is not due to any uniform, but to a polymorphous disease (pruritus, urticaria—lichenification and the development of eczema). The tormenting itching and the vegetative nervous stigmata are to be emphasized as the common symptom. The effects of diseases in hypersensitiveness of the skin are characterized by Brocq as the *réaction cutanée*.

*Read before the Association for the Diseases of Digestion and Metabolism, held in Vienna, September 30 to October 3, 1925.

In a large group of neurodermatoses the toxic effect of albuminous bodies (decomposition products of the albumin in the food) constitute the central point of the attempts at explanation. The constant entrance of alien albumin into the blood stream provides a latent tendency to disease, which leads to the outbreak of the disease from various causes.

Many years ago I advanced the etiological relationship between anomalies of the metabolism of albumin with this group of diseases. The increase in the ether sulphates and the aromatic products of intestinal decomposition were regularly present. The treatment recommended was partly intestinal antisepsis with drugs (menthol), but especially a change of the intestinal flora by means of food rich in carbohydrates and poor in albumin, by means of which the substances causing fermentation displace the germs of decomposition. The relief of obstipation is also an important byproduct.

Later on, secretory disturbances of the stomach

(Ehrman and others), pancreatic hypocholia, and other conditions were made responsible, but in the final effect the resorption of toxic albuminous bodies was decisive.

One can postulate special conditions for the penetration of the intestinal wall by intestinal toxins. Often the conditions are such that anacidity and achylia lead to hypermotility in the upper intestinal tract and also to stagnation and rectal obstipation. The toxic products of intestinal putrefaction are taken directly to the vena cava by way of the lymphatics and venous plexus and thus escape the detoxicating liver. In addition to the correction of the gastric digestion and to the intestinal antisepsis, the thorough treatment of the rectal obstipation requires the greatest attention. The most important feature is the administration of food poor in albumin.

In addition to clinical signs, a definite retention of bilirubin was found in the blood in a large group of cases as a symptom of insufficiency of the liver or an inferiority of liver function. In this condition a chronic ascending colon bacillus infection, or a latent disease of the biliary passages and disturbance of the liver function with its consequences in the skin and in the parasympathetic system, may exist.

In anaphylactic shock, as it may be produced by the antigen of the nutritional albumin, there may also appear demonstrable changes in the liver (E. P. Pick and Mautner). The author recommends treatment that stimulates the liver and biliary secretion (magnesium sulphate, formaldehyde, biliary acid preparations, and urotropin) for the syndrome of hepatic injury and dermatoses.

In four cases the intravenous administration of calcium produced a good effect through its general action upon the bloodvessels and the sedative effect upon the parasympathetic system.

Some dermatoses of endocrine origin in menstruation, pregnancy and in the climacterium (explained by the loss of the ovarian function or resorption of toxic products from the placenta) may also be mentioned. Some time ago, after an anatomic study, I explained the diffuse sclerodermia by a loss or a dysfunction of the thyroid gland, and was the first to recommend thyroid gland medication in this disease. Since then many others have carried it out. Sclerodermia is not always of purely thyrogenic nature, and examples of pluriglandular functional disturbances are well known. The combination of loss of ovarian function and disturbance of the thyroid gland is not rare, and, according to my experiences, the combined treatment with the corresponding organic preparations often shows surprising results.

The proof of the endogenic nature of some dermatoses still requires additional support. The path, which has in recent times been followed along the lines of microchemical study of the blood, promises further explanation.

The Response of the Skin to Systemic Affections*

S. GORDON, M.D.
Philadelphia

The human economy can be readily compared to a democratic government of the highest order. Each cell of the body, regardless of its situation, position or function, is considered a respectable and desirable citizen. Some cells are endowed with the power of intellect. They are placed in the anterior cranial fossæ to perform the metaphysical duties of this miniature government. Other cells possess the power of commanding and execution. They constitute the motor area of the brain. By means of the sensory and motor nerves, this executive chamber is in constant telegraphic connection with every group of cells of the body to receive impressions and administer orders suitable for the welfare of the economy at large.

The gastrointestinal tract, its accessories, and the glands of internal secretion are the various factories in which raw material is converted into food and other necessary articles to sustain the supply of energy requisite to the maintenance of the body.

The circulatory apparatus constitutes the transportation system of this government. By means of the bloodvessels and lymphatics the manufactured articles are carried from the factories direct to each cell. Nature has no use for intermediate agencies.

The phagocytes are performing the police duties. Ventilation is accomplished by the respiratory system and the cleaning department is invested in the excretory glands.

The wonderful architect of this prodigious organism believed in being prepared against a sudden attack of an unexpected enemy. He, therefore, established a standing organized army of cells on the boundary line of this government, known as cutaneous tissue, the chief function of which is protection. These cells have also the function of regulating the body temperature. Similar to a state militia, which is trained for the internal defense of a state against any hotheaded mischief makers.

The skin is also charged with the work of export and import: elimination and absorption.

This short introduction is sufficient to indicate the intimate relationship of the skin to all other organs of the body and the evident deduction that affections originating in the body will exert their influence upon the skin. An army may suffer much by fighting a strongly resisting enemy, but suffers most by lack of ammunition, food, clothes, hygiene and discipline.

The subject that I am about to discuss in this article is an exceedingly difficult one. The difficulty is due to two factors: first, many lesions of the skin show no apparent affections in the system and many affections of the system show no apparent lesions in the skin; second, almost every specialist considers der-

*Read before the Southeastern Branch of the Philadelphia County Medical Society, November 5, 1925.

matology a subject not belonging to his domain and pays very little attention to it. Even the general practitioner in his observation by inspection has in his mind only: to investigate any inequality of expansion of the chest; projection of one or both scapulæ; the presence of lateral curvatures; differences in the size of the lateral halves of the chest, etc. He observes the skin only when he has a suspicion of typhoid fever, measles, scarlet fever and other diseases characterized by definite eruptions. He makes no effort, while establishing a diagnosis of any systematic disorder, to examine the skin *per se* in order to correlate and associate any abnormalities found with that particular systemic disease. One must remove the imaginary lines of "specialties" which have been erroneously placed in the mind of the medical profession. He must study the human body as an indivisible unit. He will probably, then, agree that the skin is the most reliable indicator of the general condition of the body.

To discuss the title of this paper intelligently we must divide the subject matter into four classes.

Class A: Abnormalities of definite character in the skin associated with systemic disorders.

Class B: Abnormalities of definite character in the skin with assumed systemic disorders.

Class C: Abnormalities of definite character in the skin with no apparent systemic disorders.

Class D: Systemic disorders of definite character with an apparently healthy skin.

To describe each class fully in the limited space of an article is a matter of absolute impossibility. The author will, therefore, confine himself only to a few examples of each class with the hope that the reader will have sufficient evidence to judge upon the rest.

Class A

COLOR OF THE SKIN

1. *Pale skin.*—This usually indicates insufficient nourishment. It is generally noticed in cardiac insufficiency. It may indicate spasm of the arterioles, a decreased number of red blood cells, or a deficient amount of hemoglobin. If it comes on suddenly, internal hemorrhage may be suspected. The pallor of the skin is at times waxy in character as in nephritis, pale yellow in color as in carcinoma, ashy gray as in Asiatic cholera, or yellowish green as in chlorosis.

2. *Redness of the skin.*—This may be physiological in character as in those individuals who possess a florid complexion. The act of blushing is also a normal process. Exposure to heat or cold will manifest itself by unusual redness. A pathological diffused redness may appear after ingestion of certain drugs of the solonacea species. Anaphylaxis will give rise to redness symmetrical in distribution, known as erythema hyperemica. Local areas of redness are quite characteristic. We notice redness of one cheek in pneumonia, a flush upon both cheeks in tuberculous conditions, a dusky redness on the face of alcoholics, and the limited red areas on the nose and cheeks indicative of obstructed portal circulation.

3. *Blue or purple skin (cyanosis).*—An army may be deprived of ammunition due to one of four factors: first, defects in the transportation system; second, inability of manufacturing arms; third, adulterated material which renders the ammunition worthless; and fourth, impossibility to obtain raw material.

Examples of the first factor are any interferences with the circulation. A localized obstruction of the venous trunks of the extremities or any part of the body will produce a local cyanosis. The same is true when there is interference with the circulation of the capillaries of the lungs as in pleural effusion, pulmonary tuberculosis, or high grade emphysema.

Examples of the second factor are all the causes which are lessening the breathing surface. Occlusion of the alveoli by exudation or compression from the outside, such as pleural or pericardial effusion, hydrothorax, thoracic tumors and changes in the epithelial cells of the alveoli, will lessen the breathing.

Examples of the third factor are conditions occurring when an overdose of the coal tar products is taken or drugs which cause chemical changes in the blood, such as, hydrocyanic acid, calcium chloride, and similar drugs.

Examples of the fourth factor are those conditions which are hindering the admission of air into the lungs. Laryngeal diphtheria, edema of the glottis, foreign bodies in the upper air passages, paralysis of the muscles of respiration and drugs that depress the respiratory centre such as opium and its derivatives.

4. *Icterus.*—This is an index finger pointing to the right upper quadrant. The color of the skin usually differs from a slight lemon yellow to a brownish yellow or saffronlike tint. The change in color is first noticed in the conjunctivæ. This fact is made use of in differentiating the yellow color of jaundice from the yellowish color in chlorosis, malignant tumors, malarial cachexia, renal cirrhosis, lead poisoning and the temporary yellow color of the newborn.

5. *Bronzing of the skin in Addison's disease.*—This change in the color of the skin results from a definite systemic disorder. This brown or brownish black discoloration is due to a deposition of pigment in the deeper layers of the skin and mucous membrane.

TEMPERATURE OF THE SKIN

A cold skin occurs in all chills and rigors. It is usually associated with a poor capillary circulation. A cold skin should not be considered as an index of the internal temperature. During the stage of the chill of intermittent malarial fever, the cold skin is accompanied by a very high internal temperature. Local coldness of a surface may be due to vasomotor spasm, arterial or venous thrombosis, or any other obstruction of the circulation. A general hot skin usually exists in fevers, but it is not always so. A local area of heat indicates that some irritation has produced a vascular dilatation at that particular place.

MOISTURE OF THE SKIN

To perspire after exercising in warm weather is perfectly normal. It is also natural to sweat after hot baths, hot drinks, or strong mental emotions. Therefore, in the study of sweating as an indication

of systemic disorder, these conditions must be excluded.

An increase in perspiration indicates a weak infectious system. The night sweats of tuberculous patients, the cold perspiring skin in states of collapse, the profuse sweating at the crisis of lobar pneumonia, and the sweating in malaria may serve as examples to this statement.

Local sweating such as is noticed in bromidrosis, which is limited to the hands or feet, is a sign of general debility. Sweating of the head only is seen in rachitis. Unilateral sweating of the face or head is of purely nervous origin. It is observed in neuralgia, migraine or other nervous disturbances.

On the other hand, a decrease in perspiration is noticed in high temperatures, in increased elimination of the kidneys, bowels or stomach. It may also be seen when the skin is stretched or altered in character so as to hinder the cutaneous circulation; such is the case in anasarca or myxedema.

PURPURIC ERUPTIONS

Petechiæ and ecchymoses may be of the nature of infarctions due to lodgment of septic emboli in the arterioles, as in malignant endocarditis, septicemia and pyemia. The latter two diseases may also be accompanied by pustules, vesicles, ecthyma and papular rashes.

Purpura may also be the consequence of changes in the blood as in pernicious anemia. It accompanies infectious diseases: typhus fever, cerebrospinal fever, smallpox, bubonic plague, and all the exanthemata.

Purpuric eruptions may be produced by a number of drugs such as copaiba, quinine, belladonna, mercury, ergot and the iodides, particularly potassium iodide.

A great number of primary and secondary lesions of the skin point directly to definite systemic affections but for lack of space, I shall mention only a few examples. All the characteristic eruptions of the exanthemata, the rose spots of typhoid fever, piliosis rheumatica in acute rheumatic fever, the characteristic lesion of leprosy, the great variety of lesions known as syphiloderma due to the treponema pallidum, the pruritus pudendi, boils, and carbuncles of diabetes mellitus, the cutaneous lesions of sporotrichosis, and the herpes in pneumonia and influenza.

Class B

In this class we include abnormalities of definite character in the skin with assumed systemic disorders.

ECZEMA

Eczema occupies a considerable space in the domain of dermatology. It constitutes about thirty-five per cent. of all skin affections. It manifests itself in almost all the primary and secondary lesions. It is essentially an inflammation, nonbacterial in origin. The pyogenic organisms which produce the pustular eczema are merely uninvited guests that partake in an already prepared feast by the previously formed vesicle. All eczemas are primarily a dermatitis.

Two factors are taking part in producing this disease. An external irritant which may attack either skin or mucous membrane and a systemic predisposing factor which inhibits the reaction of the body. Whatever the irritant might be—chemical, mechanical, thermal or undigested food—it is not of itself capable of producing eczema. The dermatitis would have had a short life were it not for the systemic predisposition which has established a least resistance allowing thereby the irritant to progress until it forms an eczema. The very fact that many persons may be subjected to the same irritant and only a few manifest the eczematous eruption proves this statement to be correct.

URTICARIA, ERYTHEMA MULTIFORME, AND ANGIONEUROTIC EDEMA

These skin affections are said to be due to anaphylaxis. Fordyce, McBride, Schorer, Strickler, Sutton, and others believe that certain foods, drugs, or foreign proteids in the form of serums, when introduced into the system of certain individuals will lead to the formation of albuminoid bodies capable of producing the particular irritation. Here again it is reasonable to assume that there must be a predisposing factor in the system of those persons which prevent their bodies from counteracting the production of this irritant.

PELLAGRA

Every dermatologist believes that pellagra is a systemic disorder which manifests itself upon the cutaneous surface in a systematic distribution. The sites it selects are the dorsal surfaces of the hands and wrists, some parts of the face, scalp and neck. Until recently it was believed that this disease resulted from the ingestion of fermented maize. This has been disproved. Ormsby believes that it is due to infection of some living microorganisms. Goldberger's experimental studies prove that it is a result from insufficient proteid in the diet.

LICHEN PLANUS

This disease usually attacks persons of middle age. Children are rarely affected. Fordyce, Montgomery, Alderson and others believe that this is a systemic affection. It is probably due to nervous exhaustion.

PSORIASIS

At the present time the majority of investigators assume that this disease is due to a parasite, which invades the system. Strickler believes that psoriasis is caused by a spirochete, which is closely allied to the Treponema pallidum. He confirms his belief by the following three reasons: 1. The lesions of psoriasis tend to show central clearing similar to lesions of other bacterial diseases, such as pityriasis rosea, tinea circinata, and syphilis. 2. Psoriasis tends to recur most commonly along the lines of trauma the same as it happens in other bacterial diseases. 3. The lesions of psoriasis tend to recur because the spirochaete has not been eradicated from the system.

SEBORRHEIC DERMATITIS

This disease is said to be due to a combination of three microorganisms: Sabouraud's microbacillus, Unna's flashenbacillus and Unna's micrococcus.

HERPES SIMPLEX, HERPES ZOSTER AND POMPHOLYX

These diseases, which produce deepseated vesicles, are assumed to be of nervous origin. The irritant most probably acts on the prickle cells and liquefies them.

DERMATITIS HERPETIFORMIS

This is another disease which is believed to be a systemic affection with cutaneous manifestations. In this disease there is always an indicanuria and eosinophilia. Johnston believes that an autointoxication of the gastrointestinal tract is at times the predisposing factor.

VERRUCA

Verruca vulgaris and verruca juvenilis are the two common types. They are autoinoculable and are capable of reproducing themselves when planted on susceptible soil.

SCLERODERMA

This is assumed by the majority of investigators to be due to a trophoneurosis dependent upon changes in the central nervous system.

Class C

This class consists of abnormalities of the skin with nonapparent systemic disorders. In attributing skin diseases of this class to some defect of the system, I feel as one treading upon unsafe ground. For we are still in the dark as to the mission of the glands of internal secretion, we cannot definitely assign functions to all the varieties of the leucocytes, and we are ignorant of the variations under certain circumstances in the chemical composition of the lymph which is the sole nourishing agent of the epidermis. Yet, I am positive that every dermatologist, when confronted with a skin lesion of this character, feels that there is somewhere in the system a certain disorder which is the direct cause of it.

In the present speculative attempt to correlate a few diseases of this class with systemic affections, I must draw on the patience and sympathy of my readers, hoping that they will not perform an autopsy on the reasoning with their sharp, critical scalpels.

URTICARIA PIGMENTOSA

Under the microscope this disease resembles greatly the ordinary urticaria. The only difference is that, instead of the usual collection of leucocytes in the ordinary type, we meet here with an enormous infiltration of the basophilic leucocytes or mast cells.

It is, therefore, reasonable to assume that this disease is also due to anaphylaxis. The proteid, which becomes foreign in character by a faulty metabolism, may be acid in reaction. This excites the multiplication of the basophilic cells, which in counteracting or combining with the proteids, form the pigment.

GRANULOMA ANNULARE

This is a chronic inflammatory disease of the skin characterized by deepseated nodules which have a tendency to spread peripherally and undergo involution in the centre. Thus it forms a ring eruption.

Here again I will venture a speculation in saying that this is a parasitic disease due possibly to some fungus. We have learned that lesions due to bacteria have a tendency to central clearing. The reason for it is that the older settlers in the centre are gradually dying out, while their offspring at the periphery are still in active life. Granuloma annulare, having central clearing, is, therefore, due to a parasite. Another proof is the fact of its being sharply marginated. We know, that in fighting against a bacterial invasion, Nature makes an effort by means of leucocytes to form a barrier against the disease, in order to localize it and prevent its spreading through the system. This forms the sharp margin in all the other cases of bacterial infection. We have, therefore, a strong foothold to support the assertion mentioned above.

ICHTHYOSIS (FISH SKIN DISEASE)

Under the microscope we notice that the stratum mucosum is much thinner than normal. Its cells are flattened, the stratum granulosum is absent, and the stratum corneum is greatly thickened. We can readily see, then, that the viability of the mucous layer is very much below par. Its cells are dying right there without undergoing the normal cycle of cornification as is the case in a normal epidermis. Furthermore, cell destruction is going on so rapidly that there is no time for the stratum corneum to throw off the dead cells and so it remains thickened.

Since we know that the lymph is the only nourishing agent of the epidermis, it is reasonable to assume that a toxic element circulating in the lymph is the underlying cause of this disease. There is a great possibility that the toxin is produced by hypothyroidism because of the fact that thyroid extract administered to these patients greatly improves their condition.

Other diseases such as keratolysis, xanthoma, lichen nitidus, pityriasis rubra pilaris, acanthosis nigricans, etc., can be logically traced to systemic disorders, but for fear of drawing too much upon the patience of the reader, I will consider the three examples cited above as sufficient for this class.

Class D

This class consists of a great number of systemic diseases in which there are nonapparent disorders of the skin, and, therefore, forms the bugbear to the idea which is expressed in the beginning of this article, namely, that all systemic affections must of necessity have their influence on the skin.

Our knowledge at the present time of the gross pathological manifestations of the skin is limited to the primary and secondary lesions only. When the naked eye cannot detect any of these lesions, we are inclined to consider the skin as normal. The physiologist has not as yet given us a standard definition of what constitutes a perfectly healthy skin. Therefore, the tracing of skin pathology in such diseases as bronchopneumonia, whooping cough, bacillary dysentery, Malta fever, tetanus, actinomycosis and relapsing fever is beyond our power.

In ancient times, when the practice of medicine was exclusively in the hands of the priests, dermatology was considered the chief study of medicine and inspection was the only method of procedure in diagnosing diseases. The Bible contributes a whole chapter to the study of dermatology (Leviticus, Chapter XIII). The priest is ordered to observe the change of color of the skin to white or reddish white, to change of color of the hair to white or yellow, to look out for atrophic changes, and to watch the distribution of these pathological manifestations. The Talmud, commenting on the change of the skin to

white, mentions four white colors: snow white, white wool, white cement and egg shell. To differentiate the various shades of reddish white, the Talmud advises to take four glasses of milk and put two drops of blood in the first glass, four drops in the second glass, eight drops in the third, and sixteen drops in the fourth glass. Acabia, the son of Mahalallel, was able to recognize seventy-two different shades of abnormalities in the skin. (Talmud—Negaim, fourth tractate of Tohorath.)

This fact is mentioned to prove how skillful they were in those days in using their only method of observation by inspection. The wonderful progress which the medical profession has made since those days in diagnosing diseases by means of palpation, percussion, and auscultation, has placed inspection in the background. There was no necessity any more to strain the eyes and develop the skill of inspection. So, while we have progressed in one way, we have regressed in the other and we are looking now at the skin as at a sealed book, which cannot be read because it is sealed.

Yet, there is one fact that cannot be denied and which speaks for itself, namely: when we examine the skin of almost ninety per cent. of our patients who suffer from any systemic disease, we do not find it in good condition, though we cannot lay our finger upon any definite pathological defect.

The following interesting fact will indicate the importance of examining the skin *per se*, and the benefit that may be derived from it. For many years I was connected with the late Dr. A. Rivkees, one of the chiefs of the Eagleville Hospital and Sanatorium for Chest Diseases in Philadelphia. Our duty in this institution was to examine cases of incipient tuberculosis. In almost seventy-five per cent. of the cases we noticed an acniform eruption situated on and between the scapulæ. They vary from only a few lesions in one case to a considerable number in others. They are papular in character and differ from acne vulgaris in not being deepseated, nonfollicular and unassociated with pustules. There are no comedones, and the face is usually exempt. We have discussed this eruption and though it cannot be pronounced as pathognomonic of incipient tuberculosis, yet it is felt that its presence is more than incidental.

We are inviting the attention of the profession at large and particularly those who study the chest, to participate and express their opinion.

Trichophytosis of the Glabrous Skin as a Clinical Problem

MOSES SCHOLTZ, M.D.
Los Angeles, Calif.

Trichophytosis as a clinical problem came to the front only at a recent date, though bacteriological data on it were published as early as 1870 by Tilbury Fox. Later, Pellizari, in 1888, and particularly Djelaleddin Mouktar, in 1892, presented a comprehensive study on the dishydrotic type of ringworm. Castellani, in 1905, proved that dhobie itch was caused by trichophyton cruris, and in 1907 Sabouraud established the identity of epidermophyton inguinale. Yet it was not until a clinical study of it by Ormsby and Mitchell in 1916 (1), and later by Charles White (2), Greenwood and Wende (3) that dermatologists of this country began to take interest in trichophytosis. Since then trichophytosis as a clinical problem has steadily grown in importance and popularity among dermatologists.

This paper is limited strictly to trichophytosis of the glabrous skin. For this reason the infection of the scalp and nails will not be included. It may be remarked here that while bacteriologically there is a difference between trichophytosis and epidermophytosis, clinically they can not be differentiated; hence these terms can be considered interchangeable.

PREVALENCE AND DISTRIBUTION

The enormous prevalence of the various types of trichophytosis is not realized by the general profession. It is safe to say that trichophytosis at present makes up a considerable percentage of dermatological practice. Hazen (4), of Washington, D. C., states that trichophytosis makes up about ten per cent. of all cases in his private work. Michaels (5), of Dallas, Texas, estimates it as high as fifty per cent. Obviously, regions of warm climate will show a higher incidence of mycotic infection than cold. It is also obvious that many times more thousands of cases of trichophytosis do not reach trained dermatologists and masquerade under the names of systemic and occupational eczemas, intertrigos, etc. Still, other thousands of trichophytosis cases of low grade activity do not cause any annoyance or distress to their hosts and for this reason do not reach any medical adviser at all until a spell of hot weather or some other accidental factor brings out an acute exacerbation which forces the patient to seek medical relief.

The enormous increase in the number of trichophytosis cases in recent years is both apparent and absolute. The first is due to better means of diagnosis and early recognition as a result of the latest increase of knowledge of clinical types of trichophytosis; the second is to be attributed to the steadily growing social factors favorable to incubation, dissemination and persistence of trichophyton infection, such as social and athletic clubs, swimming pools, wearing

of wool and flannel shirts, suits and sweaters, woolen socks, unhygienic modern footwear, popularity of pet animals, etc. Thus, it can be said that trichophytosis is, to a large extent, a disease bred by civilization and, accordingly, can be best controlled by the measures of social hygiene.

SOCIAL IMPORTANCE OF TRICHOPHYTOSIS

The importance of epidermophytosis as a social medical problem is not realized by either laymen or the profession, largely because of its habitually chronic nature, and only occasional attacks of acute distress and disability; also because so many cases are not recognized as fungoid and credited to other pathogenic factors. Should it ever be possible to make a clinical and bacteriological survey of various parts of the population, a condition of epidemic, if not endemic, infection might be revealed.

If the collective total of distress, occupational disability, and financial loss caused by the various types of trichophytosis could be determined and expressed in statistical units, trichophytosis as a social medical problem would command the attention of the profession and workers of public health. Hazen, of Washington, D. C., deserves credit for being one of the first men in this country to emphasize the social importance of trichophytosis.

CLINICAL IMPORTANCE OF TRICHOPHYTOSIS

Clinically trichophytosis is also of great interest and importance for two reasons. First, because in spite of intense interest and study of trichophytosis in recent years in dermatological circles and the resulting increased clinical knowledge of the subject, the general profession remains strangely uninformed and continues to grope in the dark in regard to the diagnosis of this so widely disseminated mycosis. On the other hand, in spite of the tremendous gains in clinical understanding of trichophytosis dermatologists have not obtained a complete clinical control of this mycosis. It is a peculiar and at present rather unexplainable fact that an apparently purely local and superficial mycotic infection should be so resistant to local powerful antiseptic applications and show such a remarkable tendency to recurrence. This is particularly true in regard to the plantar and palmar types of trichophytosis. This weakness of the therapeutic end of the problem renders trichophytosis of acute interest to dermatologists as well.

CLINICAL VERSUS BACTERIOLOGICAL POINTS OF VIEW

The purpose of this paper is to emphasize the clinical point of view in contradistinction to the bacteriological. This seemingly onesided and narrow attitude is prompted by a desire to protest against a growing tendency among some dermatologists to lay undue stress on the bacteriological findings to the point of ignoring clinical data. To restore the proper balance between and the proper valuation of these points of view it seems to me would be of great service to the great body of general practitioners. Overemphasis of bacteriological findings in trichophytosis, if unchecked, may lead to the same disastrous results that the blind worship of the Wassermann test has done in regard to the clinical diagnosis of skin syphilis. The general practitioner, not encouraged to make a diagnosis on clinical data, loses all incentive and acumen for clinical observation and turns into a mere recorder of laboratory findings unable to interpret correctly his clinical observations. Such a situation is not warranted by the facts in the case. The bacteriological test is pathognomonic and conclusive, if positive, but it is not conclusive in negative aspect and it can not be used as a final diagnostic test even with the most expert technic.

Thus Hulsey and Jordan (6), of the University of Pennsylvania, in 1924, in examining the toes of one hundred students, found seventy-seven cases clinically positive. Of these fungus was demonstrated microscopically in forty-nine cases, or sixty-three per cent., while twenty-eight or thirty-seven per cent. were negative. Charles White, of Boston, in 1919, in reporting a large series of trichophytosis cases frankly admits his failure to corroborate his clinical diagnosis by microscopic and cultural findings. White concludes that he still must rely on clinical and therapeutical evidence.

James Mitchell (7), of Chicago, in commenting on White's report, states that the technic of bacteriological diagnosis of trichophytosis is tedious and requires infinite patience. In a later communication Mitchell specifically warns against mistaking intercellular spaces for fungi, which error, Mitchell states, is made with a surprising frequency by inexperienced workers. Wende (3), of Buffalo, in 1921, reporting a clinical and bacteriological study of thirty-seven cases of dermal scaling, concludes that clinical recognition of trichophytosis is fairly easy.

Thus it can be seen that under the very best circumstances the bacteriological diagnosis may be hard in many cases and in some cases unobtainable.

Aside from the technical difficulties of fungus search in individual cases it is a physical impossibility in countless thousands of trichophytosis cases to find facilities for bacteriological diagnosis. It is obvious that the bulk of these cases will have to be handled by general practitioners on clinical data only. This being the case it would seem to be rather a mistake to discourage clinical diagnosis by exaggerating its difficulties and to proclaim the dogma of the indispensability of bacteriological diagnosis.

It would be more productive of results to encourage clinical diagnosis by portraying the various clinical types of trichophytosis and outlining the differential diagnostic features. Such clinical portrayal, in my opinion, is perfectly possible. I believe that various clinical types of trichophytosis present well defined morphological entities and that in spite of superficial resemblance to various dermatoses a careful analysis of morphological details allows positive clinical diagnosis with a range of mistakes not greater than that incurred by bacteriological examination. Bacteriological examination is desirable and should be made whenever possible for completeness of the scientific record; in selected doubtful cases it may be even an absolute necessity, but for practical clinical purposes in the great bulk of typical cases (and such are the majority) it is unnecessary and can be dispensed with, just as microscopic demonstration of streptococci can be dispensed with in the average case of impetigo.

CLINICAL TYPES OF TRICHOPHYTOSIS

Clinical types of trichophytosis have been well described by various writers and to do it here again

is unnecessary. In my experience the most common variety of all is the intertriginous trichophytosis of the toes; next in frequency are the vesicular and scaly lesions on the soles of the feet; then the scaly type of tinea cruris; then the vesicular dyshidrotic lesions on the fingers and the scaly palmar cases, and the rarest of them all, the keratotic plantar cases.

It is rather strange that the literature does not mention one type of trichophytosis which I have seen repeatedly, that is, the multiple disseminated type, consisting of a number of small round and oval patches involving mainly the trunk, arms and thighs.

I have no personal experience with the lichenoid type of trichophytosis mentioned by some writers. I have seen repeatedly in cases of tinea cruris typical marginated scaly patches clear up and be followed by smooth lichenoid patches of similar size and shape. It is not clear to me whether these patches are a primary lesion caused by fungus or a secondary lichenification due to rubbing and scratching.

DIFFERENTIAL DIAGNOSIS

It has been asserted recently by several writers that the clinical differentiation of the dyshidrotic and scaly types of trichophytosis from dyshidrosis and eczema is practically impossible without microscopic demonstration of the fungus. This attitude seems to be too extreme and in my opinion is not supported by clinical facts.

DYSHIDROSIS VERSUS TRICHOPHYTOSIS

Let us consider first the question of dyshidrosis. The bacteriological demonstrations of fungi in many cases of dyshidrotic appearance have carried many observers to a sweeping statement that dyshidrosis, as heretofore described, as an independent clinical entity, does not exist, and that all cases of dyshidrosis are caused by the trichophyton fungus. In my opinion, a careful analysis of the morphological features and clincal symptomatology is sufficient to refute this extreme opinion.

Let us remember first that dyshidrosis is often, if not always, associated with hyperhidrosis. It is but natural, therefore, that dyshidrotic, i. e., hyperhidrotic, skin offers an extremely favorable soil for the implantation of trichophyton fungus. This readily explains why trichophytosis is so often associated with dyshidrosis and why the morphological features of both conditions appear so often combined and intertwined.

On the other hand, let us remember the clinical picture of a clearcut uncomplicated dyshidrosis, e. g., pompholyx: it is a sudden development of deep sago-like vesicles, uniform in size, preferentially located in the interdigital spaces of the hand, ordinarily more burning than itching. These vesicles, as a rule, do not rupture spontaneously and are not broken open by the patient (because they are not itchy) and heal up by desiccation in a few days. These attacks recur just as suddenly at various seasons, with a perfect freedom from any lesions between the attacks. The condition commonly attacks an individual below par, neurotic or run down, and improves under general tonic régime without or with hardly any local treatment. The pompholyx practically clears up as suddenly as it comes and practically never leads to eczematization.

What a strikingly different picture from the deep and superficial vesicles of various sizes, developing gradually and spreading by extension on various parts of the hands and feet, vesicles which are invariably scratched open by the patient because of the intolerable itching, and leaving the familiar scaly edge of an "epidermal collarette." Almost invariably one sees besides vesicular lesions also typical marginated, scaly, sharply defined lesions often coalescing into eczematoid patches with a smooth, glazy, denuded surface. Compare the short selflimited course of pompholyx with the stubborn persistent course of the dyshidrotic type of trichophytosis, so resistant to all kinds of local medication and the clinical difference between two conditions should be sufficiently apparent to sustain the claim of duality.

ECZEMATOID TYPE OF TRICHOPHYTOSIS

In differentiating the eczematoid type of trichophytosis from eczema it is convenient to consider separately vesicular and squamous forms. In my opinion the main and essential morphological feature differentiating common eczema, whether of systemic or local origin, from an infectious or parasitic condition, is that eczematous papules or vesicles are never discrete, that eczematous patches have ill defined borders, irregular and indefinite shape, and show a constant tendency to coalesce into diffuse extensive areas. Whenever an eczematous patch assumes sharply defined borders, particularly circinate and gyrate shapes, it is a safe clinical indication that the lesion is caused by some bacterial or mycotic agent. I have no personal bacteriological data to confirm this statement, but it has been confirmed so many thousand times by the clinical course and therapeutic test that I am satisfied to regard it as a safe clinical maxim admitting very few exceptions.

On a careful analysis of morphological details the clinical differentiation between vesicular eczema and eczematoid ringworm can be made without much difficulty in a majority of cases. In a clearcut case of vesicular ringworm uncomplicated by secondary eczematization, or better say in the early stage of vesicular ringworm before the secondary eczematization has time to develop, the vesicles are large and deep and stay discrete, while eczematous vesicles are smaller in size, more superficial, uniform in size and tend to coalesce into diffuse illdefined patches. On being ruptured trichophyton vesicles dry up quickly showing the characteristic scaly edge while eczematous vesicles on being ruptured continue to exude serum indefinitely. This differential feature has been well emphasized by Kauffman Wolff, one of the earliest observers describing vesicular eczematoid ringworm. Furthermore, in ringworm together with the vesicular lesions one can always find the well known epidermal collarette and marginated scaly edges while true vesicular eczema ordinarily retains its type and very seldom shows a coexistence of vesicular and squamous types in one case. The localization alone in many cases can assist in differentiation.

Eczema has no preferential localization. Ringworm on the contrary has a strong tendency to selective localization. Thus on the hands it commonly attacks the interdigital spaces, the palmar surface of the fingers, and the palms, and very seldom extends beyond the wrist joint. Should even vesicular ring-

worm develop a secondary eczematization, on careful search one can always detect enough of the differential features cited above to recognize trichophytosis as the underlying etiological condition.

SCALY AND SQUAMOUS TRICHOPHYTOSIS

The scaly squamous type of trichophytosis offers still better opportunities for clinical differentiation. I should again mention the sharply defined borders and particularly the circinate or gyrate marginated edges which, in my opinion, are never found in plain eczema and definitely point to the parasitic origin of an eczematous looking eruption. Another important differential feature is that scaly eczematoid ringworm presents, as a rule, much less infiltration and a much smoother, often glazy, surface than squamous eczema.

The most pathognomonic feature I would consider is the socalled epidermal collarette, the marginate festooned edges with the upturned scales attached to the outer edge and free toward the centre.

Speaking generally scaly eczematoid ringworm presents a picture of peripheral exfoliation, while in eczema diffuse infiltration and exfoliation throughout the whole area of the patch are the dominant morphological feature. The selective localization of trichophytosis on the palms, feet, groins and axillæ offers additional diagnostic suggestions.

(To be concluded)

Dermatomyositis

E. D. FRIEDMAN, M.D.
New York

ETIOLOGY

Dermatomyositis is an acute or chronic disease characterized by nonsuppurative inflammation in many of the muscles, dermatitis and edema. In many cases the affection is fatal but there is also a benign form. The first cases were described by Wagner in 1861 and later by Unverricht and Hepp in 1887. Subsequently cases were reported by Jacoby, Lowenfeld, Levy, Koster, Pfeiffer, Lorens, Boeck, Strumpell and Senator. In 1905 Steiner collected from the literature twenty-eight typical cases of which seventeen were fatal. He has since published a report on additional cases. There is a hemorrhagic type of polymyositis described by Lorens, Thayer and others, in which the dermatitis is less marked. Senator described a syndrome which he designated neuromyositis. All of these probably belong in the same group.

The disease occurs equally in both sexes, rarely in children. It is more common during the winter months. No definite cause for the disease has been found but there are various theories as to its genesis. Some ascribe the disease to infection (enlarged spleen, fever and angina). Bauer found a pure culture of staphylococci in the muscles involved. Weisner found a streptococcus. Martinotti asserts he has isolated a specific organism which he calls the micrococcus polymyositidis. But Lorens believes that organisms can hardly be held responsible for the symptoms. Unverricht thought of a protozoon resembling the gregarina found in animals, on account of the similarity in the microscopic picture of polymyositis and that of gregarinosis in dogs and horses. Pfeiffer, however, has examined a number of cases but was unable to discover any protozoon.

Senator thought of a toxic theory particularly, because he observed a case which followed the eating of decomposed crab meat. Litten also thought of intoxication, since in carbon monoxide poisoning he found marked changes in the muscles resembling those of polymyositis. Lapine believed in a vascular process, and he therefore spoke of angiomyositis. There is some similarity between the changes in this disease and those found in Volkman's ischemic myositis. Kell has described a case following the ingestion of fish. Sick reported an epidemic occurring among nurses at the psychiatric clinic of Tübingen. Myositis may occur under circumstances similar to those which produce polyneuritis (e. g., measles, gonorrhea, acute rheumatic fever, tuberculosis, influenza, gastrointestinal intoxications). Both Gowers and Oppenheim believe that exposure to cold is often a factor in the etiology of this obscure affection.

At autopsy there is usually found a large flabby spleen. The other pathological changes are those in the muscles and in the skin. Examination of the muscle obtained on biopsy shows that the muscle tissue is edematous, light yellow or red in color. At times there is noted a peculiar streaking of the surface. The tissues are usually infiltrated and soft. The consistency varies. At times they are exceptionally firm (Wagner) at other times almost fluctuating (Unverricht). There is a characteristic inflammation together with degenerative changes in the muscle fibres and interstitial infiltration. Very often there are found perivascular infiltrations and at times microscopic hemorrhages. The muscle fibres themselves are edematous and between them are often found mononuclear or polynuclear leucocytes. There may be noted also granular or hyaline degeneration. In rare cases atrophy of the muscle fibres occurs. The vessels are usually injected. The subcutaneous tissues are saturated with yellowish serous fluid. Large or small hemorrhages may be found in addition to the changes described above. In the neuromyositic form we find also neural changes with interstitial degeneration and connective tissue proliferation.

SYMPTOMS

The disease begins usually with a prodromal period. There occur malaise, fatigue, vague rheumatoid pains, sleeplessness, loss of appetite and mild

digestive disturbances. These symptoms may last from one to three weeks. At other times the disease may begin acutely with painful muscles. The pain begins most frequently in the legs and soon makes walking difficult. It is as a rule severe and variously described as drawing or sticking. Soon local swelling is found in the muscles, together with stiffness and rigidity. Fever commences and this may last several weeks. The muscles of the calves usually show massive swelling. Later the quadriceps and gluteals are involved. The muscles at first feel doughy and the skin over them shows edema, which may be so extensive that the legs assume an enormous size. There is no edema at the wrist or ankles, thus excluding the edema of nephritis and cardiac disease. The edema as a rule does not pit on pressure and it is asymmetrical. There may be puffiness of the face very much as in trichinosis. In cases of thoracic involvement there may be dyspnea and even asphyxia.

The surface of the skin in the first few days shows a peculiar glistening appearance. We may find erythema, local redness, or an eruption resembling erysipelas or urticaria. There is as a rule no itching. The rash may resemble erythema nodosum and erythema multiforme. After the disappearance of the erythema, desquamation and pigmentation occur. At times the mucous membranes show similar phenomena (stomatitis and pseudoangina).

The edema persists and the muscle swelling may even increase. The limbs can no longer be moved actively or passively and contractures develop. The inflammation may extend to the muscles of the trunk. In fact, all of the muscles of the body may be involved, including the diaphragm, eye muscles and muscles of mastication. If the muscles of the larynx or the tongue are involved there may be difficulty in swallowing with disturbance in nutrition as a result. The heart muscle has been found involved (Brauer, Jolasse and Friedman). The countenance is frequently immobile, described as alabasterlike by Oppenheim.

Paresthesias occur in the limbs. At times excessive sweating is seen. In cases of neuromyositis, definite nervous phenomena, such as more marked paresis and sensory changes occur. Later, atrophy with reaction of degeneration may be observed. The deep reflexes are generally diminished. Bladder and rectal function are not disturbed.

The spleen is often enlarged and there are evidences of constitutional infection. The latter, however, are not constant and Schnell has described cases without any fever whatsoever.

PROGNOSIS

While many of the cases are fatal in three to four weeks, either through aspiration pneumonia or paralysis of respiration, in others all symptoms may disappear and recovery may take place after several months. In some cases the disease advances from muscle to muscle and leads to a long period of disability ending either in final recovery or death. One of Steiner's patients was a negro in whom the disease lasted over a year. He finally got well. In addition to these cases with protracted course, there is another group with intermittent character.

There is a type which may be limited to one extremity and may resemble plexus neuritis. Wertheim-Salomonson reported two cases in which the involvement was limited to the left arm, shoulder and left hand. The rapidly developing edema, doughy swelling of the muscles and marked desquamation, indicated a local polymyositis. After three months there was noted muscle atrophy with partial reaction of degeneration. At the end of one year there still was a definite atrophy of the arm. In both cases the rest of the body was free.

Death comes from asphyxia, progressive asthenia, aspiration pneumonia due to disturbances in deglutition or complications in the heart. It is interesting to note that in one of Oppenheim's patients a scleroderma developed as a sequel of the disease. Our patients showed similar changes.

DIAGNOSIS

The differential diagnosis between polymyositis and polyneuritis may be difficult. The electrical tests may help; while in myositis there may be diminution of response to faradism and galvanism there are no changes in the character of the contraction or the formula. If the reaction of degeneration is present, we must think rather of neuritis. In the latter, too, there are more sensory changes. Swelling of the muscles and edema of the skin is in favor of myositis. In some cases there may be a mixed syndrome (neuromyositis).

The disease must be further differentiated from trichinosis. The latter, however, is more apt to occur in groups of individuals. There are more gastrointestinal symptoms. The edema of the eyelids is more marked and the myositic changes are seen first in the masseters, temporals, muscles of the eye and of the larynx. An increase in the eosinophilic cells in the blood is characteristic of this affection. And the trichinæ can be demonstrated in the muscles on biopsy.

Bing refers to a case of diffuse scleroderma which he observed in a thirteen year old girl in whom there developed a generalized atrophy of all the skeletal musculature. The patient also showed progressive ulceration of the skin, and the formation of fistulæ from which calcium carbonate was recovered. She died from marasmus. The pathological examination showed that he was dealing with a combination of scleroderma and polymyositis interstitialis and tendinitis calcarea. This coincidence is noted by many observers including myself. Bruhns and Neumark look upon myosclerosis or myositis as part of the syndrome of scleroderma.

CASE REPORTS

We have recently had occasion to observe two cases of dermatomyositis in the wards of Bellevue Hospital. In view of the relative rarity of this disease, it was deemed advisable to report them. In both of them the clinical diagnosis was confirmed by muscle biopsy and in one of them there was evidence of involvement of the myocardium; this was demonstrated by electrocardiographic study. Both patients illustrated the coincidence of muscular lesions and sclerodermalike changes in the skin.

Case I.—M. W., a factory worker, widow, native of the United States, was admitted to Bellevue Hospital (service of Dr. Foster Kennedy) June 11, 1923.

She died on April 15, 1924. The family history was negative. She had had one child; no miscarriages. At twelve she had had malaria. Her chief complaints were erythema of exposed parts for five months. Weakness of arms and legs for three months.

Present illness—For eight months patient had

Fig. 1.—Case I, M. W. Microscopic section showing loss of muscle striations, round cell infiltrations and mild connective tissue changes.

been occupied in "novelty works." Her job consisted of pasting packets of face powder into vanity cases. Patient suffered from an attack of grippe (coryza and cough) in February, 1923. There was a heavy feeling in the head with great fatigue and fever. She returned to work during the latter part of February. About four months before she noticed itching and erythema of face, neck and arms. For three months there had been increasing weakness of the arms and legs. At first there were drawing pains in the limbs and stiffness of the back. Now she could even lift a light weight. She could not step up the curb without pain in the anterior part of the thigh and she could scarcely walk a block. The powder was analyzed in the Chemical Laboratory of Bellevue Hospital; no arsenic or lead was found. No other employees were similarly affected. Patient had had a cough for years. Sputum had been examined repeatedly, but no tubercle bacilli were found. She had lost weight.

Physical examination—The occipitofrontalis muscle felt rigid and indurated. Pupils responded well to light but poorly to convergence. Fundi were negative. Ocular muscles were normal. There was no nystagmus. Facies were a bit immobile and puffy. There was no paralysis of the seventh nerve; sensory fifth was normal. Masseters were rigid so that the mouth could not be fully opened. Tongue protruded in median line, felt firmer than normal. Some difficulty was felt in swallowing solids. Mucous membrane of mouth was red and beefy. There was weakness of proximal muscles in the upper extremity, especially the triceps group and more so on the left. Grips were also poor. The muscles seemed fibrous. Biceps and triceps jerks were diminished. Neither arm could be extended or flexed. There was a flexor contracture at the elbow joint. Muscles of the back and gluteals were weak. Recti were rigid but their power was good. There was weakness in the lower extremities with distal involvement as well, especially in the dorsiflexors of the feet. Knee jerks were diminished. Right ankle jerk was less active than left. Abdominals were feebly present. There was no Babinski; no sensory changes of any kind. Edema was present to a slight extent in the face but more marked in the calves of both legs and on the dorsum of both feet. There was diffuse mottling of the skin and brownish pigmentation of the face and body. Some acrocyanosis of the toes and fingers. Scleroderma-like changes were noted in the skin on the dorsum of fingers and on the forehead. Heart was negative with usual methods of examination but electrocardiogram revealed low voltage and tachycardia. Lungs showed râles at the left base and dullness at the apices. Edge of the spleen was just palpable. Blood culture was negative. Temperature ranged from 98° to 101°; pulse from 96 to 116; respiration from 20 to 30. Blood sugar figures were: 115 mgms. and 110 mgms. on two occasions. The dentist found foci of infection in three teeth. X ray examination of the chest revealed increased hilus markings, moderate engorgement in lungs. No infiltration or consolidation of either lung. No evidence of cardiovascular disease was demonstrated. Phenolsulphonephthalein output: first hour, thirty per cent.; second hour, ten per cent. (total forty per cent.). Subcutaneous injections of adrenalin produced no

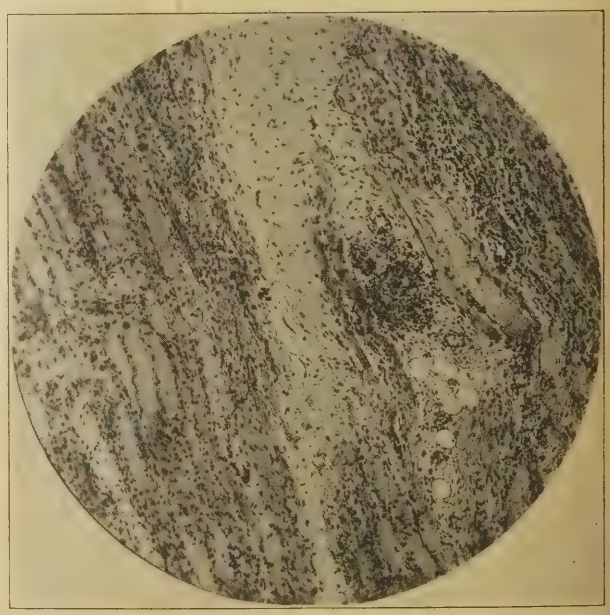

Fig. 2.—Case II, D. H. Microscopic section showing loss of muscle striations, round cell infiltrations with more marked connective tissue changes.

elevation of blood pressure or changes in the pulse rate.

Electrical tests showed diminished faradic responses in all the muscles. A diagnosis of dermatomyositis was made. A muscle biopsy was done and the clinical diagnosis was confirmed.

PATHOLOGICAL REPORT

Microscopic examination showed widespread histological changes characterized by degenerative and atrophic alterations in the muscle fibres and a variable degree of connective tissue replacement. The muscle fibres stained with different degrees of intensity and showed marked variations in size.

FIG. 3.—Case I., M. W. Showing pigmentation, edema, and somewhat immobile facies.

Some of them were cloudy and opaque, others pale and longitudinally split, so that the transverse striations were completely lost. Between the muscle fibres, in places, were richly cellular collections of small round cells. In other places, the muscle fibres were separated by proliferating fibroblasts or by fibrillar connective tissue. In still other places, the muscle tissue was completely replaced by rather broad, ribbonlike collections of fibrillar connective tissue. The bloodvessels were injected and small hemorrhagic extravasations were visible. Whether the latter occurred spontaneously or as a result of traumatism produced by removal of the tissue, was not apparent. Numbers of nerve fibres were present and some of them were surrounded or even infiltrated by dense collections of small round cells of the lymphocytic type.

Tonsillectomy was performed. A lung abscess developed at the right base, with cavity formation. This finally led to the patient's death.

On account of the progressive asthenia, the low blood pressure and the pigmentation, the question of adrenal lesion was entertained but the blood sugar studies showed no hypoglycemia nor was there any pigmentation in the buccal mucosa.

Arsenical and lead neuritis were also thought of but neither form of toxemia could be demonstrated. Infective neuronitis and polyneuritis were eliminated by the absence of any definite neurological findings.

CASE II.—D. H., plumber, fifty-four years of age, married, native of United States, was admitted to Bellevue Hospital (service of Dr. W. K. Draper) October 2, 1922. Died, December 13, 1922. The family history was negative. He recalled no diseases of childhood. The general health had always been excellent. He had typhoid at sixteen. There was no history of lead poisoning, no accidents or operations. He had gonorrheal infection thirty-five years ago. Lues was denied. The chief complaint was general and progressive loss of strength.

Present illness.—He began to feel tired and weak in June, 1922. Since August 1st, he had not been able to work because of increasing loss of strength, and he rapidly became bed-ridden. Both arms had become stiff. He experienced no pain except when his limbs were moved. There was general soreness of the muscles and joints. He felt drowsy all the time, but could not sleep. He had no headaches. For several weeks he had noticed involuntary twitching in the muscles, and said that his face became puffy in the middle of August. He had also noted swelling of both legs, and arms from the shoulder to the elbow. He suffered from dyspnea on exertion. There were no urinary symptoms.

Physical examination.—A poorly nourished white male lying quietly in bed. He appeared chronically ill. There was rather marked seborrhea of scalp. Corneal reflexes were present, no ocular palsies; pupils were equal, left slightly irregular; both responded actively to light and accommodation; discs were well outlined. Retinal arteries were somewhat tortuous; veins were not distended. No spots of hemorrhage or exudate. Face was asymmetrical. appeared slightly puffy, left side smoother than the right. The patient drew up right angle of mouth a little better than the left. Palpebral fissures appeared about equal. Winking reflex was somewhat diminished.

There seemed to be increased thickness of the

FIG. 4.—Case I, M. W. Showing pigmentation and edema.

skin and subcutaneous tissue on the right side of the face and neck, especially about the angle of the jaw. Several teeth were missing. There was rather marked pyorrhea, gums bled easily. Tongue was small (not atrophic) and moist, protruded in the midline; exhibited fine tremor. Pharynx was moderately congested; pharyngeal reflex normal. Tonsils were cryptic, not enlarged; several small patches

of follicular exudate were noted on the left tonsil. Chest was symmetrical, respiratory excursions rather limited on both sides. Breathing was thoracic in type, breath sounds distant, vesicular, no râles, resonance throughout.

Pulses were equal, regular, tension not increased; temporals slightly tortuous. Apex beat in fifth space four inches from midsternal line, first sound loud, muscular; short, soft systolic murmur at the base to left of the sternum; aortic second sound louder than pulmonic second. There was weakness of abdominal recti, no tenderness, rigidity or masses. Spleen was not palpable. Considerable erythema about the shoulders and over the back was noted, and some scattered areas of dermatitis over the face, sternum and arms. There was no enlargement of the glands.

The patient suffered from marked muscular weakness of the entire body; he was unable to move about in bed. There was considerable weakness of both sternomastoids, both trapezii, left more than right. Left latissiumus dorsi appeared weaker than right. Marked weakness of all muscles of the upper extremities existed, extensor muscles of forearms weaker than flexors. Weakness in legs appeared to be about the same on both sides, and all the muscles seemed involved. Both forearms were considerably swollen. Skin subcutaneous tissue and muscles had a doughy feel and exhibited marked pitting on pressure. There were scattered areas of skin and subcutaneous tissue that pitted on pressure and other areas in which the skin appeared to be bound down. The anterior thigh muscles felt hard and could not be poked up by the fingers—apparently fibrous replacement of muscle tissue. Elbows could not be fully extended because of pain and contracture of muscles. There was considerable atrophy of all muscles of the lower extremities with less edema than in the upper extremities. No hard masses or nodules could be felt in the muscles.

No ataxia or tremor was noted. Deep and cutaneous sensation were preserved throughout. Patient complained of rather marked pain on deep pressure over the muscles. Biceps and supinator jerks were slightly hyperactive, equal; left triceps jerk active, right not obtained; abdominals not obtained; cremasterics present and equal. Suprapatellar and infrapatellar reflexes were quite active, apparently equal. Achilles reflexes were active and equal. Plantar responses were normal. He answered questions readily and accurately; attention was slightly diminished. Speech was thick and at times hesitating. Responses to test phrases were fairly good.

A clinical diagnosis of dermatomyositis was made. Blood pressure was 124/68. Urine was negative. White blood cells were 9,500; polynuclears, 65 per cent.; lymphocytes, 35 per cent.; red blood cells, 5,600,000; hemoglobin, 80 per cent. Ears showed evidence of old otitis. Larynx not clearly seen because of patient's inability to open his mouth widely, but larynx appeared normal except for some thickening and redness of mucous membrane. Masseter muscles were indurated; patient could open the mouth only three fourths of an inch.

Repeated neurological examinations revealed no abnormalities aside from a slight hyperesthesia of the fingers and the dorsal aspect of the hands.

The patient received a series of fibrolysin injections without benefit. Later there were noted in the medial part of the deltoid muscles and in the left quadriceps, enlarged, firm, fusiform swellings, apparently in the muscle tissue.

On November 29, 1922, a muscle biopsy was performed. The pathologist reported chronic myositis.

The patient lost ground, breathlessness developed and he suffered much discomfort. Large moist râles were found scattered posteriorly over both lungs. Pulse was of fair quality. He was unable to swallow anything, and had to be fed by gavage. A second blood examination revealed the following: White blood cells, 16,600; polynuclears, 86 per cent.; lymphocytes, 8 per cent.; small mononuclears and transitionals, 6 per cent. The patient went into coma. The pulse became small and of poor quality. Signs of consolidation became evident in the right lower lobe. Temperature, 103.8° (terminal pneumonia). The patient died December 13, 1922.

During the course of the patient's illness, his temperature ranged from 98° to 92.2° except for the last four days when it rose from 99.6° to 103.6°. Pulse ran from 64 to 120, respirations 18 to 38.

MICROSCOPICAL REPORT

Microscopic examination of the muscle tissue in this case shows practically identical changes with the one previously described, although in this particular case connective tissue replacement had occurred to a far greater extent, being represented by broad bands of pale, poorly staining and poorly nucleated fibrillar connective tissue.

Unfortunately, permission for autopsy was not obtained in either case. In view of the recent work on nonmedullated innervation of striate muscle, it was thought that possibly part of the increased tone of the musculature might have been due to hyperadrenalism with resulting stimulation of the sympathetic tonus.

I wish to express my indebtedness to Foster Kennedy and William K. Draper for permission to report the cases from their respective services and to Douglas Symmers, director of laboratories of Bellevue Hospital for the pathological studies.

Historical Medicine

An Historical Analysis of Laënnec's Scientific Work

CHARLES GREENE CUMSTON, M.D.

Geneva, Switzerland

René Théophile Hyacinthe Laënnec (1781-1826) was born in Brittany, a country which has given birth to numerous noted men in philosophy, politics and science. It is my purpose in this paper to examine the principal scientific contributions of this illustrious physician, not merely with the intent of praise, but to point out his mistakes as well. His writings essentially pertain to pathological anatomy and semeiology, hence I shall envisage these two branches of medical science in their various aspects. For that matter they lend mutual aid to each other and in respect of each Laënnec made them equally brilliant in his *Traité d'auscultation*, the analysis of which forms the basis of the present paper.

However, before proceeding to the examination of his most important contribution to medical science, it is only proper to refer to some more or less noteworthy contributions from his pen written early in his professional career and which, it must be said, announced the budding genius.

LAENNEC

(From a painting by Dubois in 1812)

Early in 1804 Laënnec presented a paper to the Society of the Faculty of Medicine on what he called "vesicular worms," principally those attacking man. He describes several new species pertaining to the genus Cysticercus. His article contributed to the *Dictionnaire des Sciences Médicales* in 1812 is an elaboration of the paper of 1804. More fortunate than those who preceded him, he demonstrated the existence of the male and female organs of generation in Ascarides lumbricoides; the article may be read today with great profit.

His work on the membranes of the brain is important, while the synovial capsule lying between the humerus and the acromion apophysis was first brought to light by him. Furthermore, while still a student, Laënnec gave us our first inkling as to chronic inflammation—tuberculosis—of the peritoneal cavity which before him was regarded as an inflammatory process of the stomach, omentum, small intestine, mesentery and bladder.

Laënnec upheld two theses—as was customary in his day—before the Faculty of Paris—in 1804, for the degree of doctor of medicine. One was written in Latin, the other in his vernacular. In the former he fears not to maintain that Hippocrates never existed, that the writings attributed to him were written before the Peloponnesian war, and he is inclined to suspect that the word Hippocrates was, by the ancient physicians, used like the denomination of Pharaoh for various kings ruling Egypt. All this is merely due to youth, and further commentary is quite unnecessary.

In his thesis written in French, Laënnec rapidly reviews the doctrines of Hippocrates in respect of the practice of medicine, and after having pointed out that the Father of Medicine looked upon fever as a simple process, always identical and only differing in type, he reproaches him for not having developed a complete system of nosology. It must be candidly admitted that this assertion is not lacking in exactitude, but nevertheless is far from just. All those since the days of Hippocrates who have attempted to generalize and systematize the medical sciences have ended by so greatly differing from each other that, instead of coming to the truth, they have given rise to a thousand and one contradictory theories—frequently foolish—the consequences of which have, to say the least, been very dangerous for the practice of our profession.

Although the two theses in question can hardly be recommended for their wisdom and that moderation of judgment that Laënnec later on developed, they nevertheless show that he was a student well versed in the classical languages and that he possessed an independent mind.

The discovery, in 1806, of melanosis is one of the most important in general pathology. In point of fact it cannot be strictly called a discovery, because Bonet, Malpighi, Bartholin, Morgagni, Lorry and Haller had recorded instances of the process. However, Laënnec was the first to give an exact description of this pathological change and gave it the name of melanosis. He considered it an accidental tissue and a variety of cancer.

This opinion was accepted by Meckel, Walther and Alibert, but was forcibly denied by Gohier of Lyons, and especially by Breschet. In his paper published in 1821, Breschet shows that the melanotic deposit generally occurs in the adipous cells although like Laënnec he observed this morbid product in most of the tissues composing the living body. But far from regarding it as pathological tissue or a type of cancer as did his predecessor, he proved that it was a simple deposit of the coloring matter of the blood and fibrin. Laënnec was wrong in his conjectures in respect of the primal formation and nature of melanosis, but

we cannot contest the fact that he was the first, at the beginning of the nineteenth century, to draw attention to this morbid process which had been forgotten for a long time, while the practical considerations he draws from subjects affected with this morbid change are still quite valid at the present time.

Laënnec was happily inspired when in 1812 he stated in his article in the *Dictionnaire des Sciences Médicales* that the routine performance of autopsies would one day reveal all the various lesions of the viscera. At this time he divided all the morbid organic changes into four groups, viz.: 1, changes of the nutrition; 2, changes in shape or position; 3, changes of texture produced by external agents; 4, changes resulting from animated foreign bodies. At the time this classification was regarded as very defective. In the first place monsters are not included, while considerations in respect of the laws of organogenesis are completely neglected. And what is more, this classification reposes upon two very different bases, since one is physiological, the other nosological. There is no doubt that Laënnec was not very well satisfied with it, yet it must be said that his division of morbid tissues into analogous and heterogeneous was fortunate.

To Laënnec is due our first knowledge of encephaloid and colloid cancer, whose characters he described with matchless clearness and precision. He regarded them as morbid products entirely foreign to the tissues in which they developed and this opinion prevailed regardless of the arguments put forward by Broussais, Breschet, Ferrus, Andral and Cruveilhier against it.

In Cayol's translation of Scarpa's work on hernia, Laënnec has added a note on a new type of hernia he had occasionally met with to which he gives the name of extraperitoneal.

And lastly is to be mentioned a very interesting paper published by Laënnec in the *Bibliothèque Médicale,* in which the writer exposes with great equity Gall's system from the viewpoints of physiology and anatomy. The first part of the paper is a model of clearness, while the second is filled with a warmth of expression not usual in this great physician's writings. This paper reviews all the objections put forward against the famous, yet paradoxical, doctrine of the German physiologist and its author was, I believe, the first to show that the fundamental basis of phrenology is to be found in the writings of the Islamic physicians.

A new and brilliant impetus was now to be given to practical medicine and hypotheses were to become restricted, at least in respect of a numerous and important class of diseases—I refer to the pathological phenomena arising within the thorax. All this was due to Laënnec and his stethoscope.

The question has often arisen as to whether or not auscultation was really due to Laënnec and if he only perfected this diagnostic procedure. Many have affirmed that auscultation was known to the physicians of antiquity and that they employed it currently as a means of diagnosis. but I have never been able to discern any really convincing proof of this supposition. It is true that in the Hippocratic collection mention is made of rumbling noises in the thorax and rough respiration heard when the chest walls do not contract, etc., but who can maintain that Hippocrates or other ancient physicians ever detected a crepitant or bronchial râle? It may, perhaps, be admitted that the ancient practitioners were not completely ignorant of auscultation and that in some circumstances they practised it, but I am unable to believe that they made it a science and a sure diagnostic procedure.

I believe that Bayle was the first modern physician to listen to the thorax with the ear in the diagnosis of diseases of the heart and Laënnec was familiar with this fact which he admits in his book, and says he only imitates Bayle. But where Laënnec was original and inventive was to apply auscultation to the study of diseases of the lungs, a procedure which had served him well in distinguishing the circulatory sounds. Laënnec I think was wrong in believing that his stethoscope was the most essential part of his discovery and many historians of medicine have stated that auscultation was merely a chance discovery, yet nothing can be further away from the truth. Let me quote Laënnec where he tells how he invented his stethoscope:

"In 1816 I was consulted by a young person presenting general symptoms of heart disease, but on account of obesity the application of the hand (over the thorax) and percussion gave little result. The age and sex of the patient prevented me from making the kind of examination referred to when I recalled a well known acoustic phenomenon. If the ear be applied to the end of a piece of wood a pin scratch can readily be heard on the other end. I thought that perchance one might resort to this (physical) property with success. I took a notebook and rolled it into a tight roll and applied one end over the precardiac region and my ear to the other and was both surprised and satisfied to hear the heart beats more clearly and distinctly than I had ever been able to by direct application of the ear (to the chest).

"Hence I presumed that this means might become a useful method, not only applicable to the heart beats, but also to all movements which produce sound within the thoracic cavity and consequently for exploring the respiration, voice—and perhaps even the fluctuation of fluid collected in the pleura and pericardium.

"With this conviction I at once began at the Necker Hospital with a series of cases which resulted in the discovery of new and sure (diagnostic) signs for the most part easy to detect, rendering the diagnosis of nearly all diseases of the lungs, pleura and heart more certain and perhaps more particularized than surgical diagnoses made by the sound or finger."

. . . . . .

"The first instrument I used was a roll of paper having sixteen lines in diameter and one foot in length composed of three quires of paper tightly rolled and held together by a sheet of paper glued over all, each end being evened with a file. No matter how tightly rolled there will always remain a central canal three or four lines in diameter. . . . This fortuitous circumstance offered me, as will be seen, the opportunity of making an important discovery, viz.: that this central canal is absolutely necessary for the exploration of the voice (sounds in the thorax). A completely solid body is the best instrument for exploring the heart. If really necessary it can be used for the voice (sounds) and for detecting râles, but the

two latter phenomena are heard with greater intensity by means of a perforated cylinder hollowed at the end to about one and a half inches deep.

. . . . . .

"Consequently at present I use a wooden cylinder sixteen lines in diameter and one foot long with a central canal three lines in diameter. . . . At first I did not consider it necessary to give a name to such a simple contrivance but others thought differently and I heard it called by various improper and barbarous names such as sonometer, medical trumpet, etc. Therefore I gave it the name of *stethoscope* which appeared to me better to express its principal use, as I shall show it can be used for other purposes than exploration of the chest."

At present it must be recognized that Laënnec is, at least among us moderns, the real inventor of pulmonary auscultation. But this is not all; he made it *a science*. His book entitled *Traité d'auscultation médiate*, regardless of its modest title, is a complete treatise on diseases of the chest. However, semeiological researches represent the most interesting portion of the book, likewise the most original. When published, the book caused a profound sensation throughout medical Europe and can at the present time be read with profit and interest. I shall now attempt to give an idea of this work in order to show the greatness of the services Laënnec rendered the medical profession of all time and in so doing I will briefly refer to the state of medicine in his day in order that the reader may better understand the importance of Laënnec's researches which required three years to accomplish with results that the genius of man had not been able to attain in twenty centuries of labor.

The *Traité* is divided into two very distinct parts, namely, diseases of the lungs and affections of the heart, and we will follow this division in what we have to say.

Among the various affections of the respiratory tract there are some which were very inexactly understood at the beginning of the nineteenth century. For example, pulmonary emphysema had almost entirely escaped the attention of physicians; its etiological factors and anatomical changes were unknown. The correlation of its symptoms with the lesion characterizing the process had not been perceived. Laënnec's teachings showed that it was one of the commonest results of bronchial catarrhs and the profession learned, not without astonishment, that the majority of dyspneas which for years had been included in the generic name of asthma frequently were due to pulmonary emphysema.

None of the dogmatic schools of antiquity had referred to pulmonary edema, their remarks only bearing upon hydrothorax, although a few of the more modern writers have mentioned it. Laënnec was the first to describe this morbid process, but he was wrong in considering that it was essentially chronic in its evolution. Before the advent of the stethoscope reports of cases of pneumothorax were extremely uncommon, although Itard, a contemporary of Laënnec, had written a short dissertation on the subject. Riolan (1577-1657) had remarked that in some cases which he supposed to be "hydropsy of the chest," air escaped under pressure when puncture was done, instead of pus or serous fluid. Willis (1621-1675) has left us a very remarkable case of hydropneumothorax successfully treated by the operation of empyema, while Combalusier (1713-1762) refers to puncture of the thorax in a case of suspected empyema which gave exit to air. Hence it is clear that Laënnec was not the first to describe this pathological process, but we are compelled to admit that he alone described the diagnostic signs for detecting this lesion, namely, extreme sonority on the affected side and complete absence of the respiratory sounds, excepting at the roots of the lung.

Partial pulmonary gangrene was hardly known until Laënnec described it, although Bayle (1622-1709) had described some of its effects, but he gives a false idea of this morbid process since he regards it as a kind of pulmonary phthisis.

Pulmonary apoplexy (infarct) was hardly known as only two or three examples had been recorded. Its symptoms were likewise unknown because, in these cases, the patients who went to bed in apparent perfect health, were found later dead in bed. The anatomical changes and diagnostic signs of this process are very well described by Laënnec. Before his time the profession had more or less complete notions in respect to pleurisy and pneumonia and in practice were usually able to make a differential diagnosis between the two diseases, but theoretically their distinctions were, to say the least, most defective. If, for example, we consult Cullen (1710-1790), the following is to be found. Under the name of pneumonia, the Edinburgh professor comprises all the inflammatory processes involving the pulmonary parenchyma and the pleura, because, says he, there is no sign by which one may exactly determine the seat of the lesion. Sydenham (1624-1689) looked upon pleurisy and pneumonia as the consequences of an inflammation of the blood, while Stoll (1742-1787) supposed that all these affections were dependent upon a bilious diathesis; Morgagni (1682-1772) believed that "peripneumonia" was not distinct from pleurisy and von Haller (1708-1777) professed the same. Sarcone attempted to show that both affections were identical, while Portal (born 1742) affirmed that pleurisy did not essentially differ from pneumonia. Von Haen (1704-1776), who never believed in the identity of the two processes uselessly employed great sagacity in attempting to determine the characters properly belonging to each with an attempt at making a differential diagnosis which, of course, was unsuccessful. Then Laënnec took up the problem and by combining all the data offered him from the study of pathology, percussion and above all auscultation, he solved it in a most satisfactory way.

It would be idle for me to enter into detail of all the signs that Laënnec chose and so happily analyzed and used by him for outlining an exact symptomatology. It is quite sufficient to say that he pointed out that egophony and absence of respiratory sounds, excepting at the root of the lung indicate pleuresy, that a decrease of the respiration and the crepitant râle signify pneumonia and that in both diseases percussion dullness exists.

Chronic pulmonary phthisis and catarrhal processes were confused. Cullen was mistaken when he thought he could differentiate phthisis from chronic catarrh by affirming that in the latter process there never was hectic fever. Sauvages (1706-1767) described twenty

kinds of phthisis but made no attempt to differentiate them from bronchial catarrh. It is clear that Portal had no exact ideas in respect of phthisis, since he states that forty patients out of a total number of one hundred and eleven cases he reports, were radically cured.

The definition of phthisis as given by Thomas Reid can be quite as well applied to chronic catarrhal processes and the English physician made useless attempts to distinguish pus from mucus in expectoration. Dumas, of Montpellier, following Reid's example, employed all sorts of reagents in an attempt to discover the characters properly belonging to pus and mucus. Avenbrugger never applied his method to the study of pulmonary tuberculosis.

Morton (1635-1698) surpassed all the Dogmatic writers and various practices which, before Laënnec, composed the history of this disease. He described the general symptoms very well and he carries the diagnosis as far as it was possible before the discovery of percussion and auscultation. Then Laënnec in his turn, at last put an end to the uncertainty of science and his teachings on pulmonary tuberculosis form the basis of all works on the subject ever since.

That the ancient physicians were aware of some of the forms of this disease there is no doubt and according to Hippocrates himself a tumor first develops in the lung accompanied by a dry cough; it later on softens and ends by causing consumption. In the book entitled: *De morbis,* there is a passage of a few lines describing tuberculous ulceration of the lung with great clearness and exactitude. In Bonet's works some examples are given of organic changes evidently the result of this morbid process.

Morgagni has given very few details on the subject; he only dissected one cadaver of a tuberculous subject because he feared contracting the disease which, in his day, was regarded as contagious. Finally, we have those observers whose names have already been given who attempted to throw light on the symptoms, causes and treatments of an affection which is still one of the great scourges of the human race.

(*To be concluded*)

Contributors to Medical Science

John Baptist Morgagni

Morgagni was one of the greatest anatomists who ever lived and did more than anyone else to place morbid anatomy on a scientific basis. His observations on morbid anatomy, as testified by the many parts of the body to which the name has been given, and the connection of the appearances presented with the phenomena of disease, hold their value unimpaired up to the present time, because they were the result of able and patient investigation into the various conditions of the human economy illumined and stimulated by the fire of genius.

John Baptist Morgagni was born at Forli, Italy, on February 25, 1682. His father died when he was a child, but his mother, a woman of superior intelligence, and possessed of great will power, superintended the education of her son and encouraged and helped to cultivate the taste he manifested for study. Although young Morgagni was not a youthful prodigy, he made great progress in languages and the belles lettres and distinguished himself in philosophy, a study much favored in the schools and universities of his time. He, however, chose medicine for a profession, and at the age of sixteen took the degree of Doctor of Medicine at the famed University of Bologna, near which Forli was situated. Among his teachers were the well known Antonio Maria Valsalva, Hippolito Francisco Albertini and John James de Sandris. Morgagni seems to have been a model student. His memory is said to have been remarkable. An affection of the eyes, brought about by too close application to work, compelled his abstention from study for a time: a return to his native place and rest effected a cure. Upon his return to Bologna, he assisted Valsalva in his anatomical researches on the ear, and made most of the preparations described in Valsalva's work *De Aure Humana.* He filled the place of Valsalva during his absence from Bologna, becoming exceedingly popular as a lecturer, being eloquent, apt at description, and illustrating his subjects by a variety of preparations. Valsalva it may be said, was one of the distinguished pupils of Malpighi, an earlier and great Italian anatomist, and was "demonstrator anatomicus" in the School of Bologna.

When Valsalva was transferred to Parma, Morgagni succeeded him as demonstrator of anatomy. When only twenty-four years old, he was made president of the Academia Inquietorum and is said to have established the custom of exact anatomical observation rather than that of abstract discussion which had been the vogue formerly. He gave up his post at Bologna and occupied himself during the next two or three years in Padua and Venice with anatomical studies, in Venice with fishes, and with chemistry and pharmacy. During this time he also attended the lectures of the most celebrated teachers of the universities.

Then for three years he practised medicine in his native town of Forli with great success. However, he wearied of this work; no doubt he found that the sphere for the employment of his great gifts was too limited and he came again to Padua where he had a friend, Domenicho Guglielmini. Guglielmini died in 1711, was succeeded as professor of anatomy by Vallisnieri, leaving the chair of theoretical medicine vacant to which Morgagni was appointed. He came to Padua in his thirty-first year and taught brilliantly there up to the time of his death sixty years later. When he had been in Padua for three years the Venetian Senate promoted him to the chair of anat-

omy. Among his predecessors in this chair had been Vesalius Fallopius and Fabricius. He made a lasting friendship with Lancisi, and assisted him in his *Explanation of the Tables of Eustachius,* printed in 1714. Morgagni seems to have had a genius for friendship, and was popular with all classes of society. He lived in the pontificate of Clement XI, XII and XIII, and Benedict XIV. The latter made mention of him in his work *De Beatificatione Servorum Dei.* In his profession he was contemporary with and esteemed and admired by Valsalva, Albertini, Lancisi, Verheyer, Heister, Ruysch, Boerhaave, Mead, Senac, Haller, Meckel, Le Clerc, Fantoni, Nigrisoli, Michelelotti, Mollinetti.

Shortly after his return to Padua he married a lady of Forli by whom he had fifteen children. Although Morgagni was a widely read, learned and cultured man, and one whose acquirements extended far beyond the province of medicine, his main object of study was anatomy. His whole life was devoted to the elucidation of morbid anatomy. The value of his researches was widely recognized in his lifetime, and his name was entrolled as a member of the Academia Naturæ Curiosorum in 1708, of the Royal Society of London in 1724, and of the Academy of Sciences of Paris in 1781, he being named as the successor to Ruysch. He was also made a member of the Imperial Academy of St. Petersburg in 1735, and of the Academy of Berlin in 1754.

In short, his fame spread throughout Europe, and the inhabitants of his native city proud of their countryman erected his bust in the principal palace years before his death. He died on December 5, 1771, nearly ninety years of age.

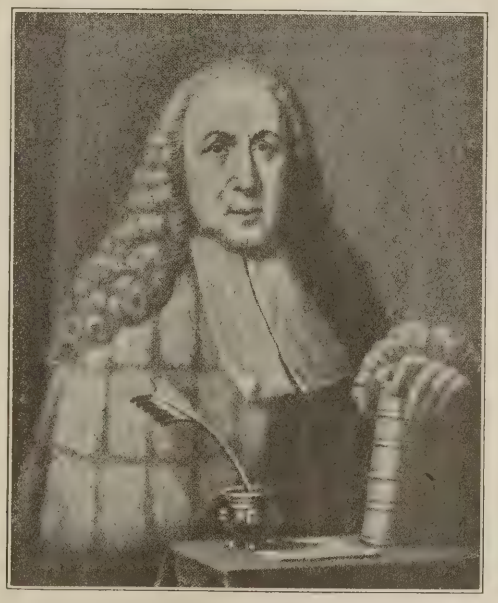
These lines from Dryden's Œdipus, apply well to the passing of Morgagni:

> Of no distemper, of no blast he died,
> But fell like autumn fruit that mellowed long
> Ev'n wondered at because he dropped no sooner.
> Fate seem to wind him up for fourscore years,
> Yet freely ran he on for ten winters more,
> 'Till like a clock worn out with eating time,
> The wheels of weary life at last stood still.

He was of fine stature, robust constitution, blond with blue eyes, and of an open and agreeable countenance.

It now remains to enumerate the works which came from his pen. They comprise the *Adversaria Anatomica* which work contributed to establish the fame of Morgagni both at home and abroad. It contains a variety of observations on minute anatomy. *The Adversaria* were six in number and were printed at different periods and places. The first at Bologna in 1706, the second and third at Padua in 1717, and the fourth, fifth and sixth, also at Padua in 1719. They were collected and printed at Leyden in 1723-4 and again in 1741, which is the best edition. *The Epistolae Anatomicae* and *Nova Institutionum,* are also valuable and have been printed frequently. He also edited and wrote a part of Valsalva's works. His chief work unquestionably is *De Sedibus et Causis Morborum per anatomen indagatis,* published first in 1761, the author being in his eightieth year. In ten years it was reprinted several times, three times in four years. Latin, original edition, French, English and German. One of the best editions is that by Chaussier and Adelon, printed in Paris in 1820. A good translation was made in English in 1769, a work now remarkably rare.

This work formed an epoch in medicine. Although the normal anatomy of the body had been discussed comprehensively and to some extent exhaustively by Vesalius, Fallopius and Harvey no one had described systematically the anatomy of diseased organs and parts. Morgagni in fact, revolutionized the study of morbid anatomy in much the same way as Vesalius his great forerunner had revolutionized normal human anatomy. Vesalius and Morgagni were the great anatomists of all time. It may be interpolated here that Morgagni who was at first inimical to the teaching of Vesalius became one of his devoted followers. Morgagni in one of his letters to Glaub in 1732, states that he has decorated his room with portraits of several men of eminence whose achievements had fired him with zest for work, and that among these portraits was one of Vesalius.



MORGAGNI

The five books which make up *The Seats and Causes of Diseases Investigated by Anatomy* contain altogether 640 dissections, subjects taken from all ranks of life from cardinal to peasant figure in this unique gallery of the dead. The work gives a vivid idea of the wonderful range of Morgagni's scholarship, indeed as is often the case with the learned, the books suffer somewhat from prolixity. While he had a fitting conception of the great importance of morbid anatomy he did not attempt to unduly exalt it or dissociate it from clinical and practical medicine. His work shows that in his day medical science had not become so largely technical and mechanical as it has become at the present time.

Symptoms were regarded by Morgagni in their proper light as "the cry of suffering organs" and not grouped into separate diseases. Morgagni initiated the point of view that the late Sir James MacKenzie developed that symptoms should not be the sole object of treatment and that primary causes should be sought. Morgagni may be termed the father of morbid anatomy as Vesalius may be designated the father of normal anatomy. The fate of these two masters of anatomy was very different. While Vesalius died a comparatively young man far from home and in tragic circumstances, Morgagni died honored and loved after passing the whole of his long life in peace and prosperity.

Editorial Articles

"FROZEN ENDOWMENTS"

Recently an appeal has been made public, signed by a distinguished group of medical men, urging that endowments for medical research, treatment, or education, be kept free from narrow limitations and rigid conditions. The men backing this appeal include presidents or expresidents of the American Medical Association, the American Surgical Association, the Society of Clinical Surgery, the New York County Medical Society, the American College of Surgeons, and the National Tuberculosis Association. Among the individual names are those of William J. and Charles H. Mayo, George W. Crile, George Emerson Brewer, Samuel A. Brown, Charles Loomis Dana, D. Bryson Delavan, Arthur B. Duel, Walter B. James, Emanuel Libman, James A. Miller, Bernard Sachs, J. Bentley Squier, George D. Stewart, William G. Thompson, and Linsly R. Williams.

The appeal states that institutional orphanages, frequently with endowments attached, have multiplied at the rate of one about every fifteen days over a thirteen year period. But the supply of orphans to fill them shows signs of diminishing, due to the effect of the campaigns against diseases causing death in middle life, of the decreasing mortality of parents during the infancy of their children, of mothers' pensions in preserving children from becoming institutional charges, and of the trend toward the placement of orphans in private homes rather than in public institutions. "Without deprecating the excellent work of many 'asylums' for orphans," the report states, "it appears demonstrable that changes in the size and nature of the problem and in the manner of caring for dependent children has tended to lessen the necessity for new orphanages, as compared with other urgent social needs." This is only one illustration from many cases.

The elasticity of the community trust plan for the administration of permanent funds for public purposes is commended as a means of forestalling the obsolescence of endowments. Dr. Walter B. James has accepted membership upon the distribution committee of the recently formed New York Community Trust by appointment of the Academy of Medicine, in response to an invitation from the trustees of the Trust. Under the community trust procedure, various financial institutions agree to hold and invest the principal of endowments, but to disburse the income only as directed by a central distribution committee. This committee executes the wishes of the original founders, and has power to effect such amendments in the provisions of the grant as may be made advisable by unforeseen changes in conditions. Thus a method is provided of bringing together endowment funds of whatever size, giving them permanent administration, and preserving them from becoming moribund. Each fund, large or small, constitutes an independent memorial. Each is placed for investment and safekeeping with any one of various national banks and trust companies, acting as trustees of the community trust. A more detailed statement of the community trust may be secured from Dr. Walter B. James, 7 East Seventieth Street, New York.

Such a plan is on the face of it a step in the right direction. State, county and municipal institutions that have outlived their need or usefulness would do well to take notice, as was instanced by the case reported recently in the daily papers of a county almshouse that had been kept open for more than a year and at a cost of several thousand dollars for *one* inmate. Both private and public funds and endowments should be so regulated that their expenditure may be adapted to timely needs instead of to outworn and useless purposes and ideals, that were doubtless high and praiseworthy at the time when the bequest was made or the fund appropriated, but are no longer in accordance with social requirements.

MANIPULATIVE SURGERY

Not long ago George Bernard Shaw, who is always ready to let fly a dart at the medical profession, declared in the British public press that surgeons, as a rule, had not sufficient manipulative skill to fasten their own shoe strings properly. Although the statement, of course, was not taken too seriously there was enough truth in it to arouse the medical profession. At a recent meeting of the Medical Society of London a symposium was held dealing with manipulative surgery. The discussion was opened by Mr. Rowley Bristow and Mr. R. C. Elsmlie well known orthopedic surgeons.

Mr. Bristow allowed that the criticisms aimed at manipulative surgery as done by medical men were, on the whole, largely justified. He complained that the methods of manipulative treatment were not absorbed into the general practice of medicine because the teachers in the medical schools did not recognize their value. Surgery in the medical schools and hospitals was taught on the grand scale. There would seem to be no room and no time for adequate attention to be given to those minor disorders which cease to be

minor as soon as the student leaves the hospital and goes into practice. This is to say that general practice is not made up of surgery on a grand scale but rather of these minor disorders and injuries with which the general practitioner is unable to cope successfully for the very good reason that when a student he was not afforded the opportunities for thorough training in their diagnosis and proper treatment. Mr. Bristow expressed the opinion that it would be wise for those who control medical education to examine their premises and to consider whether in the huge curriculum which now obtains, sufficient time and care is given to the instruction of the student in these minor ailments which form so large a part of practice.

One surgeon who joined in the discussion said bluntly that this ignorance of things that really matter in general practice was due largely to the fact that there was too much scientific training. He would not have stretched the truth greatly if he had affirmed that too much attention was paid to that branch of medical science which happened to be the vogue or the fashion at the time. Obsessed by his training to the effect that the methods of modern medical science were supreme, the practitioner was diffident about dealing with cases and sought other opinions and relied more and more on mechanical means of diagnosis. This speaker said that there had been great manipulative surgeons before the use of the x rays. Thereby inferring that while modern scientific methods and surgery had advanced greatly, knowledge gained from clinical experience had retrograded in a similar proportion and that the general practitioner nowadays was not the reliant and skilful man he was formerly because he had not been trained properly in clinical methods but taught to rely too greatly on others and mechanical means. Unqualified men and illegitimate practitioners of every description have taken advantage of the situation with the consequence that a great deal of the practice which should be in the hands of those who have spent long years and much money in obtaining the right to practice is being done either by those who have spent short years and less money on special work or by those who are untrained.

Of course the merits of manipulative methods are grossly exaggerated. They are useful and the general practitioner should be well trained in them but they are not panaceas for all the ills to which flesh is heir as their advocates claim. As pointed out by more than one speaker in London the publicity propaganda fostered by the lay press is a powerful weapon in the hands of the bonesetters. Their triumphs are loudly applauded and their failures not mentioned. Generally speaking, the opposite is the case as regards medical men. However, the conclusions reached at the symposium in London seem to have been that as the majority of budding physicians and surgeons will be general practitioners and not specialists, their training should fit them for the class of work they will chiefly meet with, minor disorders and minor injuries. These appear to be sane conclusions and as the situation here does not differ very materially from that in Great Britain, similar advice is applicable to those responsible for the control of medical education in this country.

WHAT IS A DEFECT?

We have endless statistics, these days, of defects and defectives. The layman is often confused and confounded by these exhibits and even the physician may gasp a little at the amazing state of affairs which is sometimes supposed to be revealed. What is a defect? Does a wart deserve the distinction, and when? Is an inequality in length of feet a defect, and which foot is defective? George Washington had a deformity of the chest. Was the father of his country defective? If so, his children might well have such an inheritance.

In the examination of children in the Scanlon School of Chicago by the Tuberculosis Association of that city "forty per cent. were found to have defective vision," though "only seven per cent. were urgently advised to have their eyes cared for." It has long been known that not more than two per cent. (if that many) of eyes are anywhere near perfect; are we to infer that the Chicago children have such superior vision? But why should only seven out of a hundred be cared for?

In one large city the seventy medical examiners of schools differed so widely as to what a defect of vision is that one found only 1.5 per cent., while another found twenty-four per cent. The range as to diseased tonsils was from two per cent. on the one hand, to thirty-five per cent. on the other; for nasal obstruction, from one to twenty-two per cent.; for decayed teeth, from eight to forty-nine per cent.; for stoop shoulders, from one tenth to nineteen per cent.; for anemia, one half to twenty-five per cent.; and for defective heart, from none to 3.5 per cent. How such an evident condition as stoop could be found 190 times to one by two examiners, or that there could be any mistaking nasal obstruction or decayed teeth seems inconceivable. Such evidence betokens either gross negligence in preparation of the examiner or equally gross negligence in examination. It indicates, incidentally, the poor class of medical examiners employed in public schools—men who have neither adequate training nor interest (further than financial). This is not the fault of the physicians, but of the schools which train and the public which likes cheap help for the care of its most important possessions—its children. It is interesting to note that those who

have had experience of the examination of children by school teachers find that, on the whole, they know their business better than the average medical examiner, and it would certainly seem impossible for them to be more wild in their guesses at what a defect may be than the doctors we have mentioned.

We are advertising heavily our annual examinations of adults. Are we any better equipped to recognize a defect in them than in school children? We cannot see that we are. Five hundred men of about the same age, at the same employment, in two large cities, were examined recently by two separate groups of specialists. According to the returns from these examinations about ninety per cent. of one group possessed diseased tonsils and ten per cent. of the other group; about eighty per cent. of one group had arteriosclerosis against about ten per cent. in the other. It is needless to say that one throat specialist had a bad tonsil bug in his brain. As regards the arterial defect, the examiner for one group depended on his touch for determining the condition of the vessels, while the other used a certain degree of blood pressure. With the mention of blood pressure we are only opening up the subject of what a defect is or is not.

We are having too much of standardization along many lines, but it would seem that there might be better teaching, undergraduate and graduate, as to what is meant by a remediable defect, for we do not consider that we should waste our time with enumerating and tabulating any that are not of such a nature as to really need treatment.

THE LEAD TREATMENT OF CANCER

Professor Blair Bell of Liverpool University a few weeks ago read a paper on the treatment of cancer by lead at a meeting of the Toronto Academy of Medicine. He asserted that he and his associates had treated cancer with some degree of success by a socalled colloidal form of lead. So great publicity was given to Professor Blair Bell's statements, in lay as well as in medical journals in this country and in Canada, that a feeling of optimism seems to have been created among some that the cancer problem had been solved once and for all.

Of course the statements made by Professor Bell warranted no such optimism as is now demonstrated by the evidence of Professor Francis Carter Wood, Director of the Institute of Cancer Research at Columbia University, who has returned recently from a visit to Liverpool, where he went for the express purpose of investigating the situation as regards the Bell treatment. It appears that, although the treatment has met with some success, the method is not unattended by danger and is certainly dangerous if the lead which is injected into the veins of the patient is not prepared by expert chemists and employed fresh. Moreover, experience is needed to judge whether full doses can be given or not, while numerous analyses must be made of patients' blood and other fluids to watch the progress of treatment and to be aware if the danger point is being approached.

As a matter of fact, the lead method is as yet in the experimental stage. The use of the drug has not been standardized nor is the preparation of lead stable. Much has to be done ere the lead mode of treatment can be brought into general use. All that can be said is that the treatment has many encouraging features and seems to be one which, if it be perfected, may improve the treatment of cancer to a remarkable extent.

THE IMPORTANCE OF FOCAL INFECTION

The part which focal infection plays in the initiation and development of disease is now being estimated with a fair degree of accuracy. In referring to focal infection it may be pointed out that it is in the mouth and immediately adjoining parts that foci of infection are most common. Many of the acute or semiacute diseases originate in the mouth, nose or throat by inhalation of microbes or germs there present are excited into activity by causes as yet unknown. It has been suggested for instance, that the inhalation of silica dust is a potent means of arousing into activity the germs of tuberculosis. This seems to be the theory that is gaining in favor, that some unknown cause activates latent germs into activity. In any event, it is of the first importance to keep the mouth and its adjoining parts as clean as possible. Not only the acute infectious diseases of which rheumatic fever is undoubtedly one and the chief cause of heart disease the most deadly of civilization which are spread by means of the mouth, but many of the chronic diseases, the joint forms of rheumatism are owing wholly or largely to germs of low vitality which inhabit the mouth, the gums for example.

Chronic rheumatism is the cause of more invaliding and disability than any disease and according to statistics gathered by the English Ministry of Health seventy per cent. of the cases of rheumatism in that country are due to infection in the mouth, largely to infection in the gums by a microbe of low vitality but of great persistence, probably a streptococcus. In the Scandinavian countries the situation is similar and no doubt it is not different, at least, to any great extent in America.

Taking all these points into consideration, it may be stated without exaggeration, oral sepsis is an influential factor in the production of disease.

In this connection attention may be directed to a powerful article contributed to the issue of this Journal of January 20, 1926, by Dr. F. G. Crookshank of London, in which he shows logically the sequence of events which may and frequently do follow oral sepsis in different forms and points out that it may be truly said that specific infections are caused by antecedent and nonspecific infections and of course as far as the practical lesson as regards the mouth, gums and adjoining parts is concerned, is to keep them clean, that is to prevent oral sepsis from gaining a foothold. In the prevention of disease and in preventing foci of infection, the care of the mouth is of first importance, because foci of infection are obviously more common in the mouth than anywhere else and because a dirty mouth may mean the poisoning of the body and a consequent lowering of its powers of resistance to disease.

GOITRE AND IODINE

There is much searching for goitres these days and much piling and compiling of statistics as to their frequency. From the nature of these statistics and from general observation we often wonder whether these students of goitre are always sure of a goitre when they see it, or whether any of us know just whether or when a goitre exists. Goitres are always found to be more common in girls, a fact which makes us feel that the question is the more apposite. Studies made thirty years ago showed that the thyroid enlarges appreciably during the time of menstruation, and, seen at this time, this temporarily enlarged organ must often be classed as an abnormally large organ, when at some other time it would be considered normal. Again, in thin persons a thyroid might seem prominent, which, when covered with abundant adipose, would be pronounced normal. There can be no exact measurements and the statistics must be very rough indeed and depend very much on the ideas of the examiners.

Certainly if New York city examiners do not see goitres more readily than those in other regions there is a considerable percentage of them among girls on the seacoast, for, according to Goldberger and Aldinger of the New York public schools, the gland was slightly enlarged in 17.2 per cent. of white girls, moderately enlarged in 2.6 per cent., and markedly enlarged in 0.5 per cent. Do twenty per cent. have goitres? The enlargement in colored girls was somewhat less frequent.

In the examination of 595,206 school children in New York State rural and smaller city schools, made by many examiners, goitre is reported as a "defect" in about 2.6 per cent., but we are not informed whether these were slight, moderate, or marked cases. In Philadelphia schools two to three per cent. has been reported as the average by many examiners for a number of years. Doubtless these were at least moderately enlarged glands or they would not have been noted in routine inspection in past years.

Dr. A. S. Jackson, of Madison, Wis., calls attention in the *Boston Medical and Surgical Journal* of December 17, 1925, to the danger from the use of iodine in the treatment of adenomatous goitre. He says: "Although I have advocated and am continuing to give iodine in definite amounts in the prophylaxis and treatment of early colloid goitre, I am not too well satisfied with my results. I have one series of at least one hundred cases in which iodine has been administered over a period of two years with little or no appreciable effect." However, "the laity as well as the profession should realize that any adult who has a goitre and takes iodine does so with considerable risk. I believe that iodine should be dispensed only on the prescription of a physician."

Dr. Jackson goes on to tell of a series of fifty cases of iodine hyperthyroidism in which the mortality was higher than for any other form of toxic goitre. He holds Lugol's solution, administered by the family physician, as responsible for six of these cases and thinks seven cases were due to the use of patent medicines. He thinks the disease a distinct entity, though resembling exophthalmic goitre in many ways.

THE INCREASE IN TYPHOID FEVER

Preliminary reports of cases of typhoid fever from the health officers of forty-one states, covering the first eleven months of 1925, show an increase over the same period in 1924 of forty-five per cent., according to a report in *Public Health Reports* for January 29th. An increase is noted in all the groups of states except New England and the Pacific coast. The increase by quarters is as follows: January to March, two per cent.; April to June, fifty-eight per cent.; July to September, fifty-four per cent.; October to November, forty-seven per cent. Some of the apparent increase, according to the report, is undoubtedly due to more nearly complete reporting of cases which has resulted from increased activity of state and local health departments and improvements in methods of securing reports of communicable diseases. This remark applies especially to some of the Southern and Southeastern states. It should be borne in mind, states the report, that the number of cases in 1924 was very low as compared with the number a few years ago. A comparison of the number of cases of typhoid fever in 1925 with similar figures for some of the States for 1915 and 1916 shows that the 1925 figures are generally lower. Records of cases which are comparable with present records are available for only a few years; but the death rate from typhoid in the registration area dropped from 31.3 per 100,000 population in 1900 to 6.7 in 1924. This indicates that the 1925 case rate would appear low if compared with rates of twenty years ago.

The New York Hospital, Duane Street and Broadway

The New York Hospital

MABEL WEBSTER BROWN, B.S.
New York

One of the chroniclers of the New York Hospital has aptly said that the history of the hospital is really that of New York City since the Revolution. Although it was organized as an institution and its charter granted before the war began, it was never used as a hospital until the war was over. But it was not the first hospital to be established in Manhattan. A primitive institution had been opened under the rule of the Dutch near Whitehall Street about 1638 to care for sick soldiers, who had previously been billeted upon private families, and for the West India Company's negroes, but this was in existence for only a few years. The primitive state of medicine and surgery at this time may be illustrated by incidents such as the following: In 1652 the Director and Council had to refuse a petition from the "chirurgians of New Amsterdam" that none but they be allowed to shave. The Director and Council "understood that shaving doth not appertain exclusively to chirurgery, but is an appendix thereto. . . No man can be prevented from operating on himself, nor to do another this friendly act, provided it be through courtesy, and not for gain, which is hereby forbidden." It was also decreed that "ship barbers shall not be allowed to administer any potions, without the previous knowledge and special consent of the petitioners, or, at least, of Dr. La Montayne."[1]

Medical education in the colonies was almost as primitive as was the practice of the healing art. In 1767, after the British rule had been inaugurated, a medical department was established in King's College, now Columbia University. In 1769 the first graduates two in number, received their medical degrees in Old Trinity Church, where in fitting commemoration of this event, the exercises of the one hundred and fiftieth anniversary of the founding of the New York Hospital were held in 1921.

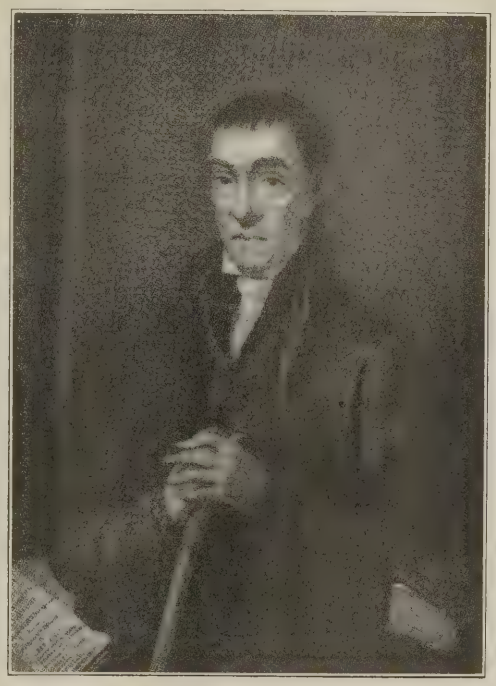
At this time the colony of New York had a population of about 200,000, about 20,000 of whom lived in the city. There was not a single hospital in which the sick could be cared for. It was Dr. Samuel Bard, a student of King's College and the London Hospital, and a graduate in medicine of Edinburgh University, who made an address at the graduating exercises urging the community to fill this crying need for a general hospital, not only for the sake of the sick, but also as a centre for proper medical education. Others prominent in the work leading to the organization of the hospital and the obtaining of a charter were Dr. Peter Middleton, Dr. John Jones, and Sir Henry Moore, Governor of New York. A charter was granted on June 13, 1771, to "the Society of the Hospital in the City of New York in America." A seal with the legend of the Good Samaritan was adopted, the original silver die of which is still used by the Society, and an annual appropriation of 800 pounds sterling for twenty years was voted by the Colonial Assembly.

[1]The Old New York Hospital, by D. B. St. John Roosa, Postgraduate, January, 1900.

The original die of the old seal is set on a pivot, so that it may be revolved above the fireplace in the Board Room of the present building of the Society in West Sixteenth Street. Framed above the fireplace is the original charter, yellow with age and stained from a burial or two for safekeeping, the first at the time of the revolution.

The location finally chosen and purchased from Mrs. Barclay and Mr. Rutgers for the hospital buildings was five acres on a slight hill on Broadway opposite Pearl Street, and on September 3, 1773, the corner stone was laid with exercises presided over by Governor Tryon. For many years the hospital was quite remote from the city, and was considered quite a distance "up town" until 1850. The story goes that one of the early staff members whose residence was at the Battery resigned his position because he found it too far to walk from his home to the hospital, and he did not wish to buy a horse.

Early in 1775, when the buildings were practically complete, a staff chosen, and preparations for receiving patients were being made, an accidental fire broke out and almost destroyed the interior. However within a year the damage was repaired and the hospital was ready to open when the Revolution broke out in 1776. With the beginning of hostilities, the New York Committee of Safety ordered the hospital to be made ready to receive Continental troops, and the first patients were some American soldiers who were wounded in an engagement between shore batteries and two British warships in the Hudson. One of the cannon balls in this fight landed on the hospital lawn. When the city was captured in September by the British, the hospital became a barracks for British and Hessian troops, and for the next seven years, it continued to perform this function, varied by occasional use as a military hospital. At the close of the war a long period of reconstruction and reorganization had to be undergone, with the result that this "asylum for pain and distress," as the Governors called it, was not opened for the treatment of patients until 1791. A few years later the corporate title of the institution was changed by the Legislature to its present form, the Society of the New York Hospital.



THOMAS EDDY

The stately old hospital buildings of grey stone, surrounded with beautiful lawns with gay flower beds and grand old elm trees, were one of the city's most admired landmarks. The grounds extended from Broadway west to Church, and from Duane Street north to Worth. There was a long walk up from John's Gate, with glimpses of the Hudson between ivy clad tree trunks and over vine covered stone walls. Tame deer greeted the stroller, begging to be fed and petted. There was a high "picket" fence, with a real gate that was locked after a certain time at night, so there was no easy getting in after hours. Also a grim Cerberus-like being recorded belated arrivals and told the tale the next day. In addition to the main hospital building, with its fine cupola, the original group included the North Building, the South Building, a laundry, large stables, and a lecture building where autopsies were held. There were five hundred beds for patients. This group housed the hospital until 1870.

A great many interesting events, historical and otherwise, were looked down upon by these grey old walls. A lot back of the hospital was so remote from human gaze that it was chosen in 1786 as the scene of a famous duel. A few years later, in a little house just behind the hospital, the famous demimonde beauty, Helen Jewett, was murdered, an event, which, with its succeeding trial, was one of the sensations of the day in New York. Perhaps the so-called Doctors' Mob was the most serious affair for which the New York Hospital was responsible. Dr. St. John Roosa's account of this is most interesting. "After the war closed," he writes, "some destitute Scotch emigrants were allowed to use the building for a place of shelter for a few weeks. The Legislature of the State, even, was accommodated with some rooms during some particular session at about this time. In the following winter, Dr. Richard Bailey of King's College occupied one or two rooms for anatomical lectures. Dr. Bailey seems to have operated upon a patient in one of the rooms, and, finding him unfit to be removed, he was permitted to attend him there until he recovered. The historian states that the public mind was somewhat startled during the winter by the rumor that dead bodies had been stolen by the medical students from the different cemeteries. One April Sunday morning in 1788—and here I follow Mrs. Lamb's history—some small boys climbed a ladder which had been left resting against one of the walls by a workman the day before, and peeped through the window to see what was going on within. A young surgeon, busy upon a subject in the dissecting room, greeted the first inquisitive youngster with the flourish of an arm—not his own—and the boy fled with the news to his father, a mason, who repeated the story to his comrades, and, seizing such tools of their trade as would best serve them as weapons, they started in a body for the hospital. Their force increased as they advanced, and the whole city was in wild tumult. The hospital was surrounded, the doors burst in, several subjects were discovered, and a collection of anatomical specimens destroyed. The mob swore vengeance upon all the doctors in the

city, and started for the house of Dr. Cochrane, which they ransacked from cellar to garrett in search of subjects. They omitted to open the scuttle and look out on the roof, or they would have discovered Dr. Hicks, of whom they were in hot pursuit, snugly hiding behind the chimney. In the height of their frenzy they passed the house of Sir John Temple, and, mistaking the name of Sir John for 'surgeon,' attacked it furiously and were just barely restrained from leveling it to the ground. As night approached the ranks of the rioters were thinned, and it was hoped the trouble had ended. But small bands patrolled the streets, and in the morning the mob was greater than ever, having been joined by sailors from the vessels in the harbor. And it proceeded at once to storm the jail, breaking the windows, tearing down fences, and threatening to drag the doctors out and hang them. Governor Clinton, Mayor Duane, Secretary Jay, Baron Steuben, Hamilton, and other prominent citizens endeavored to appease the popular fury, but in vain. Jay, in driving to the scene, was severely wounded in the head from a stone thrown through the glass of his chariot. The Mayor hesitated to give the order to fire upon the mob. Baron Steuben, in the benevolence of his heart, was remonstrating with the Governor against attempting to quell the riot with firearms, when he was hit in the forehead with a brickbat and fell bleeding to the pavement, crying loudly, 'Fire, Governor, fire!' That seems to have ended the riot."

Present Building of New York Hospital

By 1870 the financial burden of maintaining a hospital on the original spacious and valuable site became too heavy, and the Governors vacated the buildings and leased the ground on long terms, which are still being renewed from time to time. As soon as funds became available, a new hospital was built on the present site between Fifteenth and Sixteenth Streets, west of Fifth Avenue. While the hospital was being moved from lower Broadway, the demand for an emergency hospital service in that locality resulted in establishing a hospital in a disused police station on Chambers Street. This service became so important that in 1894 the Society acquired a plot at the corner of Hudson and Jay Streets and constructed a modern fireproof hospital building known as the House of Relief, which was maintained until 1919, when the property was bought by the Government since two other hospitals recently established in the neighborhood were supplying its needs.

In 1877 the New York Hospital established an ambulance service which is still being maintained, with a record of nearly two hundred and fifty thousand responses to calls to date.

An outline of the work done by the hospital in aiding other institutions is given by Mr. Edward W. Sheldon, president of the Board of Governors, in his historical address at the celebration of the one hundred and fiftieth anniversary of the founding of the hospital. The Governors cooperated in the establishment of the New York Dispensary in 1795. From 1801 to 1827 the hospital took in the Society of the Lying-In Hospital and its operations; the New York Lying-In Asylum from 1823 to 1825; the New York Eye and Ear Infirmary from 1824 to 1826; and the New York University Medical School from 1866 to 1869. In 1792 a step of tremendous import was taken in the assumption of the first care in the state of the mentally diseased. In 1799, a few months after Jenner had announced his great discovery in London, Dr. Valentine Seaman introduced vaccination for smallpox into America at the New York Hospital. There, from 1798 to 1870, a special hospital service for sailors was maintained. "There, in 1816," to quote from Mr. Sheldon, "the philanthropic Quaker, Thomas Eddy, a Governor, the treasurer, and afterward the president of the Society, who had made a study of the reforms then in progress in France and England under the direction of Philippe Pinel and William and Samuel Tuke, presented a memorable report to the Governors in which he advocated a radical change in the medical treatment of mental diseases. This resulted in the establishment, in a spacious country site on Morningside Heights, of a separate department of the Society known as the Bloomingdale Hospital, open to the whole country, which has ever since cared for the mentally afflicted on a humane and scientific basis, and has gained a world wide reputation."

In 1816 the New York Hospital issued an American pharmacopeia that had been prepared by Dr. Samuel L. Mitchill and Dr. Seaman primarily for the use of the staff, but which became a standard

for most of the country until the first United States pharmacopeia was prepared in 1821 under the supervision of a convention of state medical associations in Philadelphia presided over by Dr. Mitchell.

Among operations performed for the first time at the New York Hospital were those of ligature of the common carotid artery by Dr. Wright Post in 1813; of the external iliac artery in 1814; of the subclavian artery in 1817, and the ligature by Dr. Valentine Mott in 1818 of the innominate artery. There Dr. Francis U. Johnson as early as 1832 abandoned the old method of treating fevers by depletion. In 1835, after an inquiry into the cause of erysipelas in the surgical wards of the hospital, a detailed report was made and published with definite recommendations for rearrangement of wards, greater cleanliness, larger and more competent force, etc.

Especially in its early days was the New York Hospital a centre for medical education. At the old Broadway Hospital three hundred students regularly attended the clinics held in the main building, and as many more those held in the new South building. In 1796 a medical library was established, which was open to the public. When the financial burden of its maintenance became too great, the collection of 23,000 volumes was given to the New York Academy of Medicine. In 1840 a pathological cabinet was inaugurated, which in 1901 had become so large that it could no longer be accommodated, and so was divided among the laboratories of various medical colleges.

Second only in importance to the training of doctors has been the training of nurses. As early as 1799, Dr. Seaman gave a course of lectures and practical demonstrations of the care and nursing of maternity cases. In 1877, when the New York Hospital moved into its new quarters on Sixteenth Street, it established a school of nursing which is still in operation. This is the second oldest institution of the kind in the country.

In all the wars that the country has suffered, the New York Hospital has played its part in care of the sick and wounded and service on the field. In the Spanish-American war, much service was rendered in the typhoid epidemics at some of the camps and at various posts and camp hospitals in Cuba, Porto Rico and the Philippines. During the World War a unit from the New York Hospital maintained in France at Chateauroux United States Base Hospital No. 9, which cared for a total of 15,000 medical and surgical cases. Another contingent from Bloomingdale Hospital's staff went abroad and served with merit in the care of those suffering from war neuroses and psychoses.

In times of epidemics the New York Hospital has also played a large and valuable part in care of patients, both within and outside its walls. This has been the case from the time of the early yellow fever and cholera epidemics, through those of infantile paralysis and influenza, down to the present day.

In addition to the general medical and surgical divisions of the hospital, and the special departments already mentioned, the hospital maintains a Division of Laboratories, a Department of Urology on the recently established Brady Foundation, a Department of Radiology, a Social Service Department, and various out patient clinics. Mr. Sheldon states that from the opening of the hospital in January, 1791, until January 1, 1921, the Society treated in all its departments a total of 2,015,000 patients.

No outline of the history and work of the New York Hospital would be complete without a sketch of its chief department, that for mental diseases, namely, Bloomingdale Hospital, at White Plains. It was in the old Broadway Hospital, in September, 1792, that the Governors directed the admission of the first mental case. After a few years a special building was constructed for such cases, but this soon proved too small since its limit was seventy-five patients; so, when Thomas Eddy presented the results of his study of the care and treatment of the mentally diseased to the Governors, in which he urged the purchase of a large tract of land near the city and the erection of suitable buildings, remote from the congested life that he foresaw would mark the lower part of the city, his advice was acted upon. A tract of land was bought on the corner of Broadway and 116th Street, where the library of Columbia University now stands. In 1868 a tract of 300 acres had been bought at White Plains, New York, since the Governors had realized that a site for such an institution in New York city must at some time become impracticable; but it was not until 1894 that plans were completed, new buildings constructed and the new plant ready for the reception of patients. This is the site which Bloomingdale Hospital now occupies.

So we see how the history of the New York Hospital is in a sense that of the city of New York since the days of the Revolution. The closing sentences of Mr. Sheldon's memorial address bear witness to this. "The origin of the institution," he writes, "had so lofty a purpose, its affairs were administered with such devotion the personnel of its Board of Governors, its membership, and its medical staff, were so representative of the best the city contained, that the Society touched the community closely. Its attending physician was President Washington's medical adviser during his official residence in New York; another attending physician and one of its attending surgeons ministered in 1804 to Alexander Hamilton's fatal wound; in 1824, while visiting in New York, General Lafayette became our guest and honorary member; in 1862 the surgeons of the visiting French fleet were entertained at the hospital; and at all times that building was the Mecca of the medical profession throughout the country...But no account of the achievements of the hospital in the century and a half of its corporate life could be complete which did not award the fullest recognition to the devoted band of physicians and surgeons, the first of whom by their commanding vision and influence brought the institution into being, and who, with their successors during the intervening generations down to the present time, have made its great accomplishments possible. An adequate appraisal of the work of those brilliant practitioners and teachers must be intrusted to a competent hand, and will some day, we may hope, be duly executed. But the admiration and gratitude we all feel for the noble service which they have gratuitously rendered for the relief of the sick and for the advancement of medical education, must not remain unexpressed. They have included the flower of the American medical profession, and they have left an ineffaceable imprint on the development of the art of medicine."

News Items.

New York Birth Rate.—The birth rate in New York State in 1925 was the lowest ever recorded—20.6 per thousand population.

McClintock Foundation.—A memorial foundation for the study of alimentary diseases has been endowed by a gift of one half million dollars, from the widow of the late Andrew Todd McClintock, M.D., of Wilkesbarre, Pennsylvania.

Darling Prize.—As a memorial to the late Dr. Samuel T. Darling, of Baltimore, the League of Nations has approved a prize to be awarded by the Malaria Committee of the League for research work in that disease. The fund is to be collected by private subscription.

School of Tropical Medicine.—Dr. Robert A. Lambert of New York is to be the new head of the school of tropical medicine, recently established in Porto Rico by Columbia University. This is part of a Pan-American medical centre which Columbia hopes to establish, to cooperate with the University of Porto Rico in the conquest of disease in the tropics.

Influenza.—Outbreaks of influenza are reported at widely separated places. In Texas, Houston and El Paso have been affected; in the latter city sixty teachers and over nine hundred pupils have been absent at one time. In Missouri eleven thousand cases were reported in January, the epidemic continued in February; at the little town of Sodus, New York, one thousand people, half its population, have been ill with the disease. Syracuse, New York, faces an epidemic of the proportions of 1918, and in Binghamton and Gloversville, large numbers of cases are reported.

Benefit for Physicians' Home.—Verdi's Requiem Mass will be sung by the Metropolitan Opera Company, Sunday, April eleventh, for the benefit of the Physicians' Home. The soloists will be Gigli, Easton, Mardones, and Telva. The money secured will be used toward the purchase of the estate of the late Colonel Edward M. Knox, (known as Downsbury Manor) at Ridgefield, Connecticut. This will be the Eastern unit of the Home.

Anniversary of Dr. Wilbur.—The tenth year of Dr. Ray Lyman Wilbur as president of Stanford University was celebrated by a dinner given by the board of trustees. Dr. Wilbur is an alumnus of the university.

Hospital News.—The Flushing Hospital plans a campaign, beginning May 1st, to raise $750,000 for an addition.

The Lebanon Hospital of New York will start work on its new building at Grand Concourse and Mount Eden Avenues, June 1st. Its capacity will be two hundred and fifty beds.

Montefiore Hospital of New York will build a new tuberculosis sanitarium at its Bedford Hills branch. Eight buildings for patients, connected by covered passageways, and a research laboratory, are planned, at a cost of $1,500,000.

The Holy Family Hospital of Brooklyn is conducting a campaign to raise $500,000.

The Newton Hospital, of Newton, Massachusetts, is planning a campaign to raise $1,000,000 for additions.

Personal.—Dr. John O. Polak of Brooklyn delivvered an address at the Boston Dispensary on Relation of the Outpatient Department to Community Health.

Dr. H. R. Litchfield of Brooklyn has returned from abroad and resumed his practice in pediatrics.

Dr. H. Rabinowitsch of New York has been appointed attending physician to the dispensary of the Ocean Hill Memorial Hospital.

Dr. Louis Hausman and Dr. A. M. Rabiner have received appointments as adjunct neurologists to Mount Sinai Hospital, New York.

Dr. Carleton Simon, formerly of the New York City Health Department, is planning a statistical survey of the narcotic situation in New Orleans, for the health department of that city.

Dr. Jacob D. Smith, of Shelbina, Missouri, was guest of honor on his seventy-fifth birthday, at a banquet given by residents of the town. Dr. Smith has been in practice in Shelbina for fifty-three years.

Dr. John Girdwood of Baltimore has been appointed medical examiner for the Baltimore City Service Commission.

Society News and Notes.

Dr. John Leonard Kantor of New York addressed the Philadelphia Röntgen Ray Society on March 4th, on the subject of Ileal Stasis.

* * *

A meeting of the New York Microscopical Society will be held at the American Museum of Natural History on the evening of Friday, March 19.

* * *

A meeting of the Section of Anthropology and Psychology of the New York Academy of Sciences will be held on the evening of Monday, March 22, at the American Museum of Natural History.

* * *

At the recent meeting of the New York Ophthalmological Society, the following were elected officers for 1926: Dr. John M. Wheeler, president; Dr. F. W. Shine, vice-president; Dr. John H. Dunnington, secretary and treasurer.

* * *

The Western Physiotherapy Association will hold its annual meeting April 15th and 16th, at Kansas City, under the presidency of Dr. A. D. Willmoth, of Louisville. Dr. Richard Kovacs of New York is one of the speakers.

* * *

The twentieth annual banquet of the Women's Medical Society of New York State will be held at the Hotel McAlpin, New York, March 29th. Tickets may be obtained from Dr. Harriet F. Coffin, of 426 East Twenty-sixth Street, New York.

* * *

The annual meeting of the American Stomatological Association will be held April 5th, 6th, and 7th, at the New York Academy of Medicine. An address of welcome will be given by Dr. Samuel A. Brown, president of the Academy, and the response will be by Dr. Weston D. Bayley, of Philadelphia, president of the association. Dr. H. V. VanEtten, president of the New York State Medical Society,

will discuss stomatology and general medicine, and Dr. Alfred J. Asgis, of the International Stomatological Association, will describe the history of the movement. Dr. Joseph Colt Bloodgood of Johns Hopkins University, Baltimore, and Dr. George Reese Satterlee of New York are among those who will present papers, and several prominent members of the profession will be represented in other papers and discussions. The proposed educational programme for stomatological teaching will be considered. Physicians and dentists are invited to attend the meetings.

* * *

The West Side Clinical Society of New York has elected the following officers: President, Dr. Jerome Kingsbury; Dr. George A. Schnepel, vice-president; Dr. George Stevenson, treasurer, and Dr. William B. Giles, secretary.

* * *

In celebration of the eighty-fourth anniversary on March 30 of the first use of ether as an anesthetic, the Library of the New York Academy of Medicine has on exhibition some material having to do with the life and career of Dr. Crawford Williamson Long. Dr. Long discovered the anesthetic qualities of ether in 1842, but did not make generally known his discovery until after Morton and Wells had reported it. A statue is to be erected to Long in Washington's Hall of Fame, as a memorial to his discovery. The exhibit of the Academy of Medicine contains a copy of the original report on ether anesthesia made in 1849 by the Medical Society of the State of Georgia, of which state Dr. Long was a native, in which it is declared that his discovery is authentic. A series of articles on Dr. Long's life and work by his daughter, which have been appearing in the *Annals of Medical History,* are soon to be published in book form.

* * *

The Society for the Prevention of Cruelty to Animals has just issued a fourth book of lessons for Teaching Humane Education. There is an introduction by Dr. Paul Klapper, dean of the School of Education of the College of the City of New York, giving enthusiastic endorsement to the work of the society and of the book.

* * *

The year 1926 is the seventh anniversary of the founding of the League of Red Cross Societies. An interesting outline of its history and work, past and present, appears in the *World's Health* for January.

* * *

The New York Children's Aid Society has recently completed and made public the results of a five years' study of malnutrition among school children. The society conducts ten health center schools which are attended by handicapped children, and these schools have within the past five years brought back to health more than eight thousand children. The health building work has reduced undernourishment from 41 to 16 per cent. among the children in these schools, in spite of the fact that there has been in the five years a 75 per cent. turn over of pupils.

* * *

An American Health Congress, to be held in Atlantic City during the week of May 17, is being planned by the National Health Council in order to give health workers from all parts of the country a bird's eye view of the public health movement as a whole. Among the subjects to be covered in the discussions and addresses by authorities on the various phases of public health work are tuberculosis, cancer, heart disease, blindness, social and mental hygiene, public health nursing, preventable diseases, and health education for children and adults.

* * *

The National Committee for the Prevention of Blindness has taken up its new headquarters in the building occupied by the other members of the National Health Council at 370 Seventh Avenue, New York City.

* * *

The *World's Health* for January contains a world map showing the location of the medical stations already established and to be established according to the international scheme of the Norwegian Red Cross Society for improving the health of the sailor. In response to the mandate of 1924 of the General Council of the League of Red Cross Societies, the Norwegian Red Cross Society invites the maritime countries of the world to make use of its medical stations, and to forward this invitation to every sailor. The Norwegian Red Cross states that it also hopes that similar stations will be established in the large seaport towns throughout the world.

"Say it with pearls" is the title of a new film for children dealing with dental hygiene, which has been prepared and is now being shown under the auspices of the International Dental Health Foundation for Children. The film is in six reels, each of which presents in a manner interesting and attractive to youngsters a phase of dental hygiene.

* * *

At the meeting on February 2d of the French Academy of Medicine announcement was made of the perfection of a method of vaccination against lockjaw which can be applied at the same time as antityphoid vaccine, according to a notice in the *New York Times.* The announcement was made by the inventors of the method, Zoeller of Val de Grace and Ramon of Paris, young French scientists, who have already discovered a method of vaccinating against diphtheria. The new vaccine is said to immunize for life those who have received it. It was stated at the meeting that the antitoxins had responded without exception to all the tests to which they have been subjected.

* * *

The International Medical Society, recently organized in New York, gives its first official dinner to a foreign medical representative, Prof. Léon DuFourmentel, who is in the United States on a mission from the French government. The dinner will be given at the Columbia University Club, 4 West Forty-third Street, on the evening of Wednesday, March 24th, preceding a meeting at the New York Academy of Medicine, where Dr. DuFourmentel will present a paper on The Present Status of Plastic Surgery in France. The committee on arrangements is represented by Dr. Samuel J. Kopetsky, Dr. Thomas J. Harris, Dr. Henry Paul Forbes, Dr. Frank R. Herriman, Dr. Jacques Maliniak, and Dr. J. A. Lopez.

Book Reviews

RADIOTHERAPY

La Curiethérapie des Cancers. By Simone Laborde, Chef de Laboratoire de Radiologie au Centre anticancéreux de Villejuif. Paris: Masson et Cie., 1925.

Under the rather too narrow title of *Curietherapy,* Laborde gives us a very complete course of instruction in an art which as he says himself in an interesting *avant-propos,* is still largely in a state of flux, if not of experimentation, that of radiotherapy as we call it. The various rays—alpha, beta, and gamma of two varieties, hard and soft—are discussed from the viewpoint of physics, as emanations, and from the practical point of application in the treatment of cancer. There is a very complete study of the properties of radium. A chapter is then devoted to anatomical and clinical facts about cancer, its pathogenesis and diagnosis.

After discussing the biological effects of radiations, Laborde describes the various appliances and principles of technic. He then takes up the special application to various localities. Finally, there is a chapter on complications seen in the course of treatment of cancer, and on accidents due to the handling of radioactive substances, with suggestions as to necessary precautions.

Laborde has some interesting observations on cellular modifications, on latent periods, and on the progressive desensitization, or vaccination, of the tissues to radioactive substances, which add greatly to the scientific value of his short but most interesting work.

ECZEMA AND URTICARIA

Ekzem und Urtikaria. Klinik, Pathogenese und Therapie. Von Dr. Erwin Pulay. Berlin und Wien: Urban & Schwarzenberg, 1925. Pp. xi-191.

The pathogenesis of eczema and urticaria is considered from the viewpoint of modern experimental pharmacological studies. Both conditions may be due to exogenous and endogenous causes. There must be both a receptive condition and a provocative agent. The receptive condition for eczema consists in a hypersensitivity of the epidermis plus sensory nerve endings; the receptive condition for urticaria consists in a vascular hypersensitivity. The nervous hypersensitivity is produced by endogenous factors, usually abnormal metabolic processes. Hypersensitivity is expressed clinically in increased irritability.

For the production of eczema an exogenous stimulus must attack the epidermis, including a latent eczematous condition (potential, latent eczematous); this is produced by endogenous or exogenous sensitization. Endogenous and exogenous stimuli are positive sensitizers. If there is hypersensitiveness only to certain stimuli, whether chemical, mechanical, or toxic, we may speak of idiosyncrasy.

Endogenous stimuli result in urticaria in the presence of a vascular hypersusceptibility; dermatitis results with a hypersusceptibility of the epidermal cells; pruritus results from the hypersusceptibility of the sensory nerve endings: eczema results, finally, from hypersusceptibility of the epidermis and of the nerve cells.

Urticaria and eczema may result hematogenically. The latter will result if a former primary eczema has already existed. Primary eczema, however, is the result of exogenous trauma—usually scratching.

The clinical picture of eczema includes pruritus, usually produced hematogenically (endogenous), but there is also a pruritus that is produced exogenously, which also gives rise to eczema, as in pediculosis, scabies and other local infectious diseases of the skin (pyodermias).

Idiosyncratic eczema and urticaria are part of the picture of the general phenomena of sensitization. However, only a minor part of the cases of eczema and urticaria can be considered definitely as idiosyncratic.

Anaphylaxis and idiosyncrasy are similar in nature and can be differentiated clinically in so far as anaphylactic conditions are associated with eosinophilia and general symptoms of a vagotonic character, whereas idiosyncratic conditions are localized only in a certain system of organs or in a single organ.

Thus eczema and urticaria, in the final analysis, represent conditional changes in the albumin of the cell, being governed by the laws that control the normal and pathological processes of the cell. Reversibility and irreversibility of the reactions determine the possibility of cure and of chronicity. The irreversibility that occurs with every change in condition produces cellular memory, and hypersusceptibility takes root as increased irritability in the cellular memory.

The chapter on therapy is very complete and includes much detail. Röntgenotherapy is not considered favorably.

The bibliography of both eczema and of urticaria is given and includes the literature of the world.

BIOCHEMISTRY

Applied Biochemistry. By Withrow Morse, Professor of Physiological Chemistry and Toxicology, Jefferson Medical College, Philadelphia. Philadelphia and London: W. B. Saunders Company, 1925. Pp. 958.

This is one of the best textbooks of biochemistry in English. There is a strong personal quality in the form in which the material is presented, and the experienced teacher is revealed everywhere, especially in some of the informal footnotes, which often contain information scarcely to be expected in such a text, for example, under Fats, it is mentioned that the Phoenicians discovered glass by noting that the sand under their campfires fused and made a transparent substance. Nevertheless, all these odd notes, together with the portraits of famous chemists, are useful hooks upon which the student may hang elusive facts not so fascinating and easily remembered as the example cited. The quotations as chapter headings show the scholar's interest also. The only criticism that can be made is that some of the cuts seem unnecessary. The picture of an alundum Gooch crucible, or that of a fluted filter, for example, occupies space that might well contain a little more chemistry. If the medical student absorbs half of the contents of this volume, he will be well educated in biochemistry, for no essential omissions have been

discovered, and as far as can be judged, the salient facts are simply and fully described in an easily understandable manner. The book can be highly commended as an admirable student text, as well as useful for the advanced laboratory chemist.

NEW REMEDIES

Formulaire des Médicaments Nouveaux pour 1925. Par Dr. R. Weitz, Préparateur à la Faculté de Pharmacie de Paris, Pharmacien des Dispensaires de l'Assistance publique. 31e. édition. Ancien formulaire Bocquillon-Limousin. Paris: Libraire J. B. Baillière et Fils, 1925.

Whether they order these matters better in France, as claimed, if we are not mistaken, by our Uncle Toby, is a question, when it is a matter of pharmaceutics and formularies. This little volume makes its appearance annually and is intended to keep us posted in the matter of new remedies, official and unofficial. Of late there has been such an unprecedented increase in the number of largely synthetic preparations, organic, inorganic, and of biological origin, that it is difficult to keep pace with all developments, either theoretically or in practical, therapeutic application. Weitz gives us the latest Parisian novelties, but our own modes are, one might say, a bit slighted. *A chacun son goût.* But we miss novatophan, fibrolysin, quinisal, and doubt if their respective places can be taken by *hyrganol Poulenc, dioséine Prunier,* or even *gouttes clin strychno-phosphorsinées.*

A BOOK OF PRESCRIPTIONS

Medical Formulary. By E. Quin Thornton, M.D. Twelfth Edition, Revised. Philadelphia and New York: Lea & Febiger, 1925.

The twelfth edition of this book of medical formulary claims to be revised to accord with the tenth revision of the *United States Pharmacopeia,* apparently a joke as there are preparations used in the prescriptions that have not been official for many, many years.

This book of prescriptions is perfectly absurd from the viewpoint of therapeutic or pharmacological advice in the present era of the rational treatment of disease. A few references to the contents of the book, selected at random, will show its ridiculous and ancient teachings. There are prescriptions written for morphine one eighth grain, in powders for the physician to dissolve in so many drops of water and administer hypodermically, entirely ignoring the fact of the many years of use of aseptic and cleanly hypodermic tablets. Also prescriptions are written for the druggist to put the ingredients into glass ampules, as though a druggist could do it! There is a prescription for injecting iodoform into the rectum of a baby who has diarrhea. There appears a mixture of gold and sodium chloride, sodium arsenate, barium chloride, extract of nux vomica, and extract of cannabis, in pills, for debilitated subjects with spermatorrhea. Potassium bromide is ordered in a capsule. There is a prescription for fluidextract of ipecac in five drop doses until nausea, for nosebleed. There is another for musk, mucilage of acacia, syrup and rose water to be given to a child with spasmodic croup. There are prescriptions containing seven ingredients. Enough has been said to show that the book should be a museum specimen rather than part of the armamentarium of a modern physician.

GONORRHEA IN WOMEN

Diagnose und Therapie der Gonorrhöe Bein Weibe. Sanitätsrat Dr. S. Jessner, Koenigsberg. Leipzig: Curt Kabitzsch, 1925.

This little paper covered volume is the twenty-fifth in the series of Dr. Jessner's *Dermatologische Vortrage für Praktiker.* It is written in brief, attractive style, without illustrations, but inclusive of all up to date methods of diagnosis and treatment. As is to be expected, the greater part of the work is devoted to the subject of therapy. One does not recognize anything startlingly new in the author's handling of the subject. Standard methods of therapy are advocated, among which is the intramuscular injection of milk and other foreign proteins in deep seated infections.

The German reading physician, particularly the gynecologist, will find much that is interesting and useful in this little work.

THE DEAFENED

Formulaire des Médicaments Nouveaux pour 1925. Par Dr. By Anetta W. Peck, Estelle E. Samuelson and Ann Lehman. With an introduction by Wendell C. Phillips, M.D. Paris: Libraire J. B. Baillière et Fils, 1925.

In the preface the authors tell us that this little book represents the gathered opinion of fourteen years of shared experience in a new phase of social work; "its opinions have been wrought out in spare moments, over the luncheon table, on professional journeys, and checked up by the day's work, day after day, year after year." Since the authors themselves are not in possession of the sense of hearing, they are in a position to give unique information and most valuable guidance in this new field of social work with the deafened.

In his introduction to the book, Dr. Phillips states that the day has passed when the otologist's full duty to his patient ends with a professional verdict, or with such treatment as can be administered for prevention or cure. "The peculiar psychology which accompanies the deafened condition creates the necessity for something more upon the part of the progressive otologist. . . . He should become his patient's neighbor in the highest sense, for by instituting the proper measures for rehabilitation, untold mental suffering may be avoided." The purpose of this book is to increase and strengthen a helpful interchange of work between the otologists, the educators, and the various forms of social service for the deafened.

ARMY MEDICINE

The Medical Department of the United States Army in the World War: Medical and Casualty Statistics based on the medical records of the U. S. Army, April 1, 1917, to December 31, 1919, inclusive. Prepared under the direction of Maj. Gen. M. W. Ireland, the Surgeon General, by Maj. Albert G. Love, M.C., U. S. Army. Washington: Government Printing Office, 1925. Pp. 1368.

This is Part II of Volume XV on Statistics. Part I of this volume was called Army Anthropology. This Part II completes the publication of war statistical records of the Surgeon General's Office, with the exception of special statistical material on distinct aspects of the subject. The volume is a testimonial to the tremendous amount of work and the careful and accurate recording of it necessary to the

making of such a record so that it may be practicable for comparatively ready reference use, as well as for the student or the physician professionally interested in the matter he tabulates.

The data included in the tables may be roughly classified as, 1, strength data and estimates, and, 2, sick and wounded data. A preliminary section deals with methods of assembling data in the Surgeon General's Office, followed by an explanation of the terms and methods used. An appendix gives extracts from the Manual for the Medical Department, sick and wounded reports from the American Expeditionary Forces, sick and wounded forms, report cards, etc. The preface states that for the statistical tables in this volume approximately five million statistical cards were prepared.

THE CHILDREN OF PHYSICIANS

Medical Heredity; Distinguished Children of Physicians (United States, to 1910). By William Browning, Ph.B., M.D. With an introduction by Charles B. Davenport, Ph.B., A.M., Ph.D. Baltimore: The Norman, Remington Company, 1925. Pp. 250.

This is a work unique of its kind, although analogous albeit limited inquiries, the author tells us, have been undertaken abroad. The book may be defined as a study of the intellectual tendencies of medical training and descent. The larger part of it is taken up by a classified schedule of 6,500 names with data, of sons and daughters of physicians who have played a significant or at least a useful part in the various professions, business, sociological work, societies (social, fraternal, secret), public life, military life, the navy, adventure, and miscellaneous. This section, which is very full and shows an almost incredible amount of patient research over vast areas of biographical material, is followed by comments, further statistical tables, and summaries of results. It may be of interest to refer briefly to a few of these:

More daughters of physicians are found in successful authorship than in any other line of work. They are prominent also in fine arts, in philanthropy and humanitarian work, in educational and library work, and in literature, in which last they exceed the men in number. Many sons of doctors are, most naturally, sculptors. There are quite a number of musicians and singers whose fathers were physicians, including Frank and Walter Damrosch, Marguerita Sylva, Godowsky, Fritzi Scheff, Kreisler, and Sophie Braslau. The actors and dramatists are not nearly so numerous; among them are Sir Charles Wyndham, Sol Smith Russell, Sothern, Augustus Thomas, Elsie DeWolfe and Rachel Crothers.

The list shows very few inventors. Manufacturing and business show few sons of the medical profession, but finance has quite a long list, including 120 bank presidents and heads of twenty insurance companies. Philanthropic pursuits, administration of institutions, educational activities, letters and journalism, statecraft, law, and the sciences, with the exception of mathematics, all have a large and successful following among sons of physicians. Adventurous pursuits, including exploration, discovery, travel in new lands, and pioneering of all kinds have lured many. Citations of this kind could be made indefinitely, but the book must be read and studied to gain a knowledge of its unusual interest, and the tremendous amount of work that has gone into its preparation.

Appendices list others of medical rearing, grandchildren of physicians, and long lines of continuous medical descent, including five, six, seven and eight consecutive generations of doctors. Dr. Charles Allen Porter, professor of clinical surgery at Harvard Medical School, traces his ancestry through eight generations of physicians, back to Dr. Daniel Porter, born in England, licensed in 1654, who practised in Farmington, Conn. A final appendix describes the Role of Doctors in the Lincoln Administration, an article reprinted from the *Medical Record* of October 28, 1916. Another interesting article by Dr. Browning on a phase of this same subject appeared in the *Medical Record* for October 26, 1918, under the title Some of Our Medical Explorers and Adventurers.

From this brief review of the contents of *Mental Heredity,* it is evident what value the book has, not only to physicians, but to all interested in biology, genetics, eugenics, vocational guidance, heredity and sociology in general. The style is informal and often humorous, making the book good reading in addition to its scientific interest. There are many bibliographical references to articles that have appeared in various scientific publications on medical heredity and related subjects. "Whether or not blessed with children of your own, there is a natural curiosity to see how the other fellow has made out," writes Dr. Browning in outlining the uses and purpose of his book—and this he has enabled the doctors of America to do.

Medicoliterary Notes.

Dr. Miller Reese Hutchison, consulting engineer and constituent member of the Naval Consulting Board, and for sixteen years chief engineer of the Edison laboratories, is quoted as having devised a method of carrying lines to sinking ships by means of a large kite, and also of having adapted the breeches buoy so that it may be used for saving the crews of sinking ships. Dr. Hutchison is the inventor of the automobile klaxon, the acousticon and various other devices.

* * *

The estate of the late Colonel Edward M. Knox, the hatter, near Ridgefield, Conn., has been offered for sale to the directors of the Physicians' Home, Inc., as the basis of the Eastern branch of the Home. The estate comprises three hundred acres, a mansion, and various farm houses and other buildings. Several other properties have also been offered to the directors including another in Connecticut comprising three hundred acres, and one near Winchester, Va., of the same size.

* * *

Thomas Seltzer announces for early publication a novel, *The Sunken Garden,* by the child poet, Nathalia Crane, of Brooklyn. The young author, rather than entrust her book to the tender mercies of the professional blurb writer, says the *New York Times,* her written her own description of the novel as follows: "The tense story opens at dusk with an ox eye tornado devastating a section of the mid-African coast. Lanterned by the lightning, we gain a glimpse of a youth torn from the shore of the mainland and washed upon the crags of an outlying islet. During the night the skiff of a wrecked sailing yacht drifts through the hooded entrance of the islet's lagoon. In the skiff there is the one survivor of the sea disaster, a young English girl of rank and culture. Thereafter we have the heroine and hero in a made to order Paradise, the damsel armed with

modernity and the youth the last living relic of a lost civilization. It is an idyllic tale, but packed with adventures. For in this bewitching sanctuary security is threatened by a danger dormant in the sunken garden. In this secret basin of natural loveliness the python regius, a monstrous ophidian, haunts the rim of a sullen pool. The magic of the book rests in the fact that from the first page there is a recession from all conceptions of present day life. Paul and Virginia were infants in swaddling clothes compared with the castaway and her island escort. As for Robinson Crusoe, well, he was a bachelor. In *The Sunken Garden* there is a complete cast, although some have four legs and one principal none at all."

* * *

According to British railway reports, in 1924 only one passenger was killed in a train accident. This record gives to Great Britain the world leadership in railway safety. In this century there have been two years—1901 and 1908—without a fatality, and in 1909 as in 1925 one only was killed; in 1916, 1919 and 1923 there were three deaths only. This was the case in spite of the fact that approximately one billion and seven hundred millions passenger journeys are made by train annually.

* * *

Williams and Wilkins, the publishers, announce that the title of the *American Journal of Electrotherapeutics and Radiology* has been changed to *Physical Therapeutics* on account of the unnecessary length and cumbersomeness of the former.

* * *

Recent announcement has been made of the formation in the Pennsylvania Department of Labor and Industry of a section which will deal with the problems of women and children in industry. This will be done through investigation into the status of working children within the state and active cooperation with the inspectors of the department to prevent violations of the child labor law within the state.

* * *

A new edition of James Branch Cabell's *Figures of Earth* has been issued by Robert M. McBride & Company, illustrated by Frank C. Pape, who was so successful in the well known English edition of *Jurgen*. The new edition of *Figures of Earth* contains a hitherto unpublished preface by the author.

* * *

Among the lecturers announced for the spring term of the New School for Social Research are Dr. John B. Watson, Dr. Ira S. Wile, and Dr. Frankwood E. Williams.

* * *

Lolly Willowes; Or the Loving Huntsman, by Sylvia Townsend Warner, is the story of a spinster who sells her soul to the devil. David Garnett, who is credited with having discovered the novel, writes of its author as follows: "No one would willingly risk having a waxen image of himself held by Miss Townsend Warner in front of a slow fire. Though she is not as far as I know a witch, she lives alone with a very large black dog . . . but what of that!"

* * *

In an effort to get at the real nature of its problems, Trinity Church, Pittsburgh, recently held an institute on the subject of human motives, according to the *Mental Hygiene Bulletin*. It consisted of a series of twenty-four popular addresses on present day problems, a number of which were devoted to mental hygiene aspects. The institute was held at the church and the addresses were broadcasted by radio.

* * *

Dr. Phyllis Blanchard, psychologist of the All Philadelphia Child Guidance Clinic, has contributed an interesting article on the dreams of children and their significance to the Sunday *New York Times* for February 21st.

* * *

A Few Notes Regarding Psychoanalysis is the title of a pamphlet recently issued by the Fellows Medical Manufacturing Company, Inc., of New York City. The preface states that the pamphlet is for the purpose of putting the general practitioner in possession of a working knowledge of psychoanalysis, by presenting the practical working essentials of the subject, by which the physician may introduce himself to its simpler practice, and so form a stepping stone to a more extended study of psychoanalysis.

Robert Quillen, a humorous writer of South Carolina, who recently attracted considerable attention by erecting on his front lawn a monument to Eve, the first woman, has applied for a $10,000 life insurance policy to be used as a trust fund in perpetuating the monument. Under the terms of the application flowers are to be laid regularly on the monument, the lawn mowed, trees pruned, and an annual bath given to the marble obelisk.

* * *

The transactions of the first international Conference on Sanitary Engineering held in London in July, 1924, have recently been published in book form by the Institution of Sanitary Engineers, London.

* * *

After a fixed date all Chinese women under thirty whose feet are still bound will be taxed a sum equal to three dollars a month. This is an effort on the part of two Chinese militarists, not only to add to the country's revenue, but to abolish a vicious custom which has persisted from time immemorial in China, in spite of many comparatively modern attempts to create feeling against it and so in time do away with it. Legend has it that the custom started in early times to prevent women from running away to seek adventures. It has recently been estimated that there are still seventy million pairs of deformed feet in China, and that in the coming generation there will probably be more.

* * *

From societies for the prevention of cruelty to animals we should advance to brotherhoods for the spreading among men of *correct etiquette* toward animals; for only so may we begin to glimpse a broader meaning in our sports.—*Langworthy Taylor in The Saddle Horse.*

* * *

Idiot Man, by Prof. Charles Richet, winner of the Nobel prize for physiology in 1913, is a recent publication of Brentano. It is the author's contention that man, both civilized and uncivilized, is far more stupid than the animals, and this he proceeds to point out in his new book.

* * *

To those of our profession interested in the history of medicine we would call attention to the publication of fifteenth century incunabula published by E. Droz, 13 Avenue Félix Faure, Paris (XV^{e}), as they are limited to five hundred copies each and not being advertised are known to few.

Of the incunabula pertaining to medicine which were issued last year there are two, namely, *Remedies Against the Plague,* compiled by E. Droz and Dr. Arnold Klebs, and *La Clef des Songes,* edited by Maurice Hélin. The latter work will be found of immense historical interest to psychologists as the subject of dreams holds an important place at present in this branch of medicine.

A prospectus of the forthcoming medical incunabula of the fifteenth century may be had by writing directly to the publisher at the above address.

* * *

The bicentenary of the birth of John Howard, the British prison reformer, was celebrated on January 20th at a service at St. Paul's London, followed by a meeting at the Fishmongers' Hall. The celebration was under the auspices of the Howard League for Penal Reform, which is carrying on the work begun by Howard. "Howard, whose personality is so shadowy, was a very remarkable man of extraordinary strength of will and persistence along the line of reform he marked out for himself," says the *Manchester Guardian.* "Always in delicate health he spent the greater part of his life in incessant and often dangerous travels of discovery, visiting prisons all over his native land and the continent, and slowly building up a mass of terrible evidence about their condition which formed the starting point for generations of reformers." Howard is said to have travelled fifty thousand miles, notebook in hand, visiting prisons, hospitals, lazarettos, schools and workhouses, and to have spent thirty thousand pounds sterling of his fortune in so doing. He lived upon vegetables and water, and a little bread and tea, and in spite of his poor physique came through countless hardships and dangers of infection safe until he died of camp fever in Russian Tartary.

Abstracts from Current Literature

DERMATOLOGY

Treatment of Epithelioma of the Face and Eyelid.—C. A. Simpson (*Virginia Medical Monthly,* September, 1923) states that the cosmetic results obtained with the x ray or radium in epithelioma of the lid are not approached by any other therapeutic agent. To secure a cure with either of these methods is to leave the patient's lid in almost as perfect a condition as if no neoplasm had ever existed. He regards radium as superior to the x ray, having witnessed a number of instances of failure of resolution upon intensive treatment with filtered x ray, often followed by prompt destruction and healing of the lesions with a triple strength radium plaque. The flat plaque, with the radium element covered with a rubber composition which filters out less than five per cent. of the beta rays, offers many advantages over the radium pack or needles. A metal capsule or needle filters out ninety per cent. of the useful beta rays. If the malignant lesion is extensive or very deep, however, the hard gamma ray is required for results; here it is better to employ the metal walled needles. The radium plaque also avoids the conspicuous and persistent local trauma and caustic effects always found at the seat of implantations of radium emanation seeds or radium needles. Timid and nervous old patients are far less inconvenienced by the adjustment of a small radium plaque, of the size of a finger nail to the lid with the patient seated in the waiting room or even in his own home than by being placed on an operating table and subjected to blindfolding with lead foil, etc., amid the din of whirling machinery.

Efficiency of Skin Antiseptics.—M. B. Tinker (*Annals of Surgery,* October, 1925) asserts that:

1. The superficial and deeper layers of the skin of protected areas in cleanly individuals are frequently free from bacteria.
2. If the skin be smeared with resistant nonpathogenic bacteria, soap and water scrub alone for two minutes will make it free from bacteria in thirty per cent. of cases.
3. Careful ward preparation with ether swab on the operating table is capable of giving skin free from bacteria in seventy-five per cent. of cases, and of reducing the colonies in the remainder to a maximum of three.
4. The selective action of antiseptics is so important that it seems wiser not to depend upon any single antiseptic for skin preparation.
5. Iodine preparations, picric acid, and alcohol alone which seem still to be the chief reliance in a number of hospitals, are too inefficient under ordinary clinical conditions to be depended upon for routine skin disinfection.
6. Acriflavine five per cent. proved most efficient in this series of tests, but probably its use combined with other dyes and antiseptics might be desirable. The chief drawback to the use of the dyes is their almost prohibitive cost.
7. It would probably be safer not to discard altogether the use of some of the older relatively efficient antiseptics until those used to supplant them have been given thorough clinical as well as laboratory tests in a number of hospitals.

Early Treatment of Superficial Burns.—I. S. Raydin and L. K. Ferguson (*American Journal of Surgery,* February, 1925) regard toxemia as the chief cause of the high mortality in burns; hence the prevention of its occurrence forms the most important part of the treatment. The toxin is gradually liberated from the damaged tissue and taken up by the blood stream. To combat the severe symptoms which develop a method after Robertson's of removing the circulating toxin by exsanguination, replacing the blood volume and diluting the remaining toxin by transfusion, is suggested.

As soon as possible after the patient enters the hospital all clothing is removed and an electric cabinet is placed over the bed. Although children under it are frequently irritable for the first few hours, they quickly become accustomed to the radiant warmth and later are much upset when removed, even temporarily. The heat is kept at 100° F.

As soon as the patient is put under the cabinet, the burned area is covered with gauze saturated with a solution of one half per cent. novocaine, which has had added to it ten minims of 1:1000 adrenalin to each fluid ounce of novocaine. When the patient reacts from the shock, the area of the second degree burn has sufficient anesthetization to allow one to remove the burned skin, open the blebs and remove the contained fluid with the superimposed skin without causing pain. If the burn is of the third degree, we anesthetize the patient within twenty-four hours and do a careful débridement. Ether anesthesia was used in the very young children, while nitrous oxide and oxygen was employed in older children and adults.

In the majority of cases fluid was administered only by mouth, but in those cases where rapid introduction was deemed necessary, the intravenous method was utilized. We do not believe in the use of hypodermoclysis in these cases, since it is not painless by any method.

The novocaine packs are continued for from forty-eight to ninety-six hours, depending upon the extent of the burn and the time at which débridement was performed.

When these are removed the area is sprayed every three hours with a fresh two per cent. solution of dichloramin-T. Because of the crusts which form over the area when dichloramine is utilized, it is necessary to bathe the patient daily to remove these.

In the less extensive burns we used only packs of normal saline solution and received such favorable results that we intend to use these altogether in the future instead of the dichloramine.

The diet is what we term light diet, reinforced, so as to supply as many calories as possible in an easily assimilable diet. The major caloric value should consist of carbohydrates so as to furnish available glycogen for the organism.

Should a patient be admitted after the toxemia has developed or should symptoms of toxemia develop in a case under treatment, we have practised exsanguination transfusion with considerable success. In the adult we have made no attempt to completely exsanguinate the patient, and in the child we have removed about twenty c.c. per pound of body weight. The blood was usually withdrawn from the median basilic vein and given through the saphenous vein. Where the signs of circulatory collapse appeared early, normal saline was given while the exsanguination was progressing.

If the burn was over a crease of a flexor surface, early extension or splinting was resorted to.

As soon as healthy granulations appeared in the extensively débrided cases skin graft was practised. We believe that better results are to be obtained from the use of Thiersch or whole thickness skin grafts than from the pinch grafts which are easily strangulated by the exuberant granulation tissue.

Experimental Primary Epithelioma from Micrococcus.—J. W. Nuzum (*Surgery, Gynecology and Obstetrics,* March, 1925) reports that from the result of six years' intensive bacteriological study it may be concluded that there is regularly present in both early human breast cancer and in the transplantable Crocker carcinoma No. 11 and in tumor No. 180 of the mouse the same microorganism. This micrococcus which belongs to the streptococcus group is also present in the metastatic growths in the lymph glands as well as in the cutaneous nodules in patients suffering from recurrent breast carcinoma. It has been isolated from primary breast carcinomata less than one centimeter in diameter and at a time so early in the evolution of this disease as to exclude the probability of its being a secondary invader. It has also been isolated in pure culture from a very early case of acute carcinoma in the human lactating breast where it was possible to determine the earliest histological lesions of breast cancer. The microorganism is readily isolated in tissue ascitic fluid media overlaid with solid petrolatum or paraffin oil, or still more rapidly in tall tubes of dextrose broth under partial anaerobiosis.

When injected through the nipple ducts into the breast acini of female dogs, two animals out of five surviving a sufficient length of time developed genuine carcinoma of the breast. In one animal the tumors regressed. The second dog died with generalized carcinomatosis secondary to a huge primary breast cancer.

Finally, repeated inoculations of this micrococcus into the skin of the groin of an elderly man, the subject of previous epitheliomata, resulted in the development of a typical squamous cell cancer.

While the results of these inoculations may be interpreted differently and the explanation of a chronic nonspecific irritation brought forward, the obvious fact cannot be denied by those entitled to an opinion that genuine cancer with metastases has been produced in the dog and primary cancer in man by repeated inoculations of pure cultures of the microorganism so constantly present in human breast carcinoma.

Since it has been shown that cancer may be produced by the long continued irritant action of bacteria in suitable subjects it is to be hoped that this work will stimulate others to investigate the micrococcus present in early human breast cancer which has quite generally been regarded as sterile.

Endocrine Glands and the Dermatoses.—A. Winstel (*Revue Française d'Endocrinologie,* January, 1925) collects a large number of reported cases in which organotherapy has been used with success, and pronounces the treatment in all to have been empirical. He endeavors in consequence to establish a scientific basis for the employment of endocrine extracts in skin disorders by subjecting his patients to physiological tests, including the cutaneous vasomotor reactions; the tests of vagosympathetic equilibrium with pilocarpine, atropine, adrenalin, and amyl nitrite; the functional gland tests of Goetsch, Porak, Parisot and Richard; tests of carbohydrate tolerance and of basal metabolism. He reports only those cases where a single gland alone could be incriminated and where administration of the appropriate single gland extract produced a complete cure. In this way he succeeded in attributing two cases of psoriasis, one of eczema, three of alopecia, one of prurigo, and one of bullous erythema to a hyperthyroid origin; one of alopecia to hypothyroidism; one of eczema to ovarian insufficiency; and two of eczema to pituitary insufficiency. While many cases examined failed to respond to the tests applied, the author considers his positive results sufficient warrant for holding that in some instances an undoubted causal relation exists between endocrine disturbances and skin disorders.

Skin Infection of Rabbits with Hemolytic Streptococci.—Thomas M. Rivers (*The Journal of Experimental Medicine,* February, 1925) describes skin lesions in rabbits produced by a hemolytic streptococcus isolated from a human case of erysipelas. The lesions produced by intradermal infection were of two sorts, phelgmonous and erysipelas like. An attempt to produce an immune serum by repeated inoculation of streptococci into rabbits, not as is usually done by injecting the bacteria into the blood or peritoneal cavity, but by intracutaneous inoculations, was successful, in that a true immune serum capable of warding off the injurious action of the streptococci on the skin had been developed in response to repeated intracutaneous inoculation of the organism.

Lime Dermatitis.—W. J. O'Donovan (*Lancet,* March 21, 1925) reports some cases to show that lime may play an important part in the causation of local and of generalized grave dermatitis in various occupations. Lime dermatitis is now looked for in a wide field of industrial life. The patient's trade label is often a most insufficient guide to this special industrial hazard. A small group of cases is recorded amongst "tunnel miners" not hitherto reported as liable to lime dermatitis. The types of dermatitis that may be seen are vesicular eruptions or cheiropompholyx, lime holes, seborrheic eczema, exfoliative dermatitis, intertrigo, erythrodermia, pustular follicular dermatitis, and septal perforation. Oversweating or abnormal dryness of the skin are predisposing factors. Preventive measures consist in frequent changes of all dust-laden underclothing, alternation of employment on to lime-free work, and the nightly application of emollient grease to the skin of the face, hands, and forearms.

Morbilliform Luminal Eruptions.—G. Milian (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* July 23, 1925) deems certain erythemas following on the ninth day after exhibition of luminal to be analogous to the eruptions he had previously described as following nine days after injections of arsphenamin or neoarsphenamin. These eruptions are not due directly to intoxication by the drug, but are infectious, the drug bringing into activity an infection, such as measles, which would otherwise not have manifested itself. During the war, such eruptions appeared in epidemics exclusively among men who had received arsphenamine or neoarsphenamine. A syphilitic woman, presenting a morbilliform eruption on the ninth day after an injection of neoarsphenamin, infected three nurslings, who developed measles. Along with the ninth day eruption there appears frequently a characteristic, pronounced swelling of the glands, showing that the condition is actually measles and not simply a morbilliform eruption. Measles from which an individual has suffered some years before may be reawakened—like a species of Herxheimer reaction—by drugs. A recently acquired infection, generally tonsillar, which would not otherwise have manifested itself clinically, may be similarly caused to develop. In these phenomena rupture of immunity may be a factor, especially when the immunity is weak, as when the infections have been mild or been experienced a long time before. Further administrations of the drug concerned cause fresh eruptions, but with diminishing intensity, until the fifteenth or twentieth day, when no eruption results, immunity having become reestablished. The endocrinosympathetic system may play an important rôle in the production and maintenance of such immunity, and hence in the origin of these eruptive manifestations. Arsphenamine and luminal are to be regarded as selective poisons to the endocrinosympathetic system.

Organotherapy in Psoriasis.—Spillmann and Carillon (*Bulletin de la Société française de dermatologie et de syphiligraphie,* July, 1925) report nine cases of psoriasis cured by organotherapy. In each patient careful endocrine tests were made and the selection of remedies made in accordance with the results. Tests with atropine, adrenalin, amyl nitrite and pilocarpine in each case showed disturbances of vagosympathetic tone, with varying predominance of the sympathetic or parasympathetic system. In three cases these disturbances were of endocrine origin, while in six they seemed to be idiopathic. Of the three endocrine cases, two showed dysthyrodism and one, hyperovarism. In the dysthyroid cases thymus extract failed, but recovery followed the use of pituitary extract. In the hyperovarian cases, thymus extract and sistomensine used separately failed but when combined yielded excellent results. In the six diopathic cases of vagosympathetic imbalance, comprising three each of vagotonia and of sympathicotonia, thymus extract alone proved successful. That the vagosympathetic disturbances were actually related to the skin condition was suggested by the fact that upon repetition of the tests in two patients after they had recovered the imbalance was found to have disappeared. In a more recent case showing sympathetic hypertonicity pills of pilocarpus were used with encouraging results. The above cases show that organotherapy is an important procedure in psoriasis. Where endocrine tests are negative, thymus extract seems to be the indicated remedy.

The Role of Focal Infections in the Etiology of Eczema.—John W. Visher (*American Journal of Medical Science,* November, 1925) reports five cases of eczema which were apparently caused by focal infection.

In the first three cases, recovery followed the removal of abscessed teeth. In the fourth patient, the eczema ran its course concurrently with an acute pharyngitis. In the last case, rapid subsidence of the eruption accompanied improvement of infected pelvic viscera.

2. Careful search was made in each case for other possible causes of the skin lesions, but none were found.

3. Local antipruritic treatment in four cases had no effect upon the skin lesions, aside from decreasing the scratching, and improvement seemed to occur in spite of, rather than because of it.

Lupus in Its Surgical Aspects.—W. S. Handley (*Annals of Surgery,* January, 1925) offers evidence to show that lupus is not a skin disease, but a disease of the lymphatic system not restricted to the skin, and governed as to its mode of spread by the facts of lymphatic anatomy. In support of this theory the following points are maintained and discussed.

a. Lupus is a nodular disease.

b. The spread of lupus is centrifugal but discontinuous.

c. In lupus nodular deposits may appear along the course of the trunk lymphatics.

d. Lupus may affect the glands and the internal organs.

e. Lupus is intractable by skin excision.

As regards treatment the author says:

In a Hunterian lecture in 1921 I expressed my general views on the treatment of lupus. Since I have seen no

reason to modify them, the succeeding section of this paper is a transcript from that lecture.

It is in the surgical treatment of lupus that my observations seem for the present to find their practical application. It is very necessary to recognize the existence around the apparent area of lupus of a zone of apparently normal but really infected skin. Even in the chronic forms of lupus, this zone appears to be present. The knife of the surgeon must, if possible, circumscribe this area if he wishes to avoid recurrence. Even more important is it to recognize the fact that excision of the skin alone is an irrational procedure. It is almost certain that the underlying area of subcutaneous tissue is riddled with microscopic tubercle in the form of tuberculous lymphatics, and that a corresponding area of the lymphatic plexus upon the deep fascia is infected. Whenever possible, therefore—and it can be done in all cases of lupus of the trunk and extremities—an area of deep fascia at least as large should be taken away in one piece with area of skin excised. The test of the completeness of the removal is that muscular tissue should be seen in the floor of the resulting wound.

Nonsurgical Treatment of Carbuncles.—H. S. Black and P. Black (*International Journal of Medicine and Surgery,* October, 1925) state that under x ray therapy the cosmetic results are better; the pain is relieved in a shorter period of time; there is less trauma to the tissues; there is quicker healing in the small carbuncles and no longer time required for the larger ones as compared with surgery; most of the patients can be treated as ambulatory ones; and the mortality rate is reduced, as shown in the cases reported in literature as well as our own.

As to the method of treatment the technic is as follows: They used a 9 inch spark gap, five milliamperes, a 12 inch skin distance and a filter of one half millimetre of copper. The time of exposure varied from twenty to thirty minutes in our later cases, but in our first few we did not use so long a time, as we were careful not to do harm. This latter reason explained why we had to give a few of our cases more than one treatment, though the longest period of time in any one case totaled sixty-nine minutes. This patient should have had two applications of twenty-five minutes each, and our result would have been more rapid and the number of treatments would have been reduced from five to two. We have learned not to hesitate about giving a large enough dose at the initial sitting, always allowing the rays to penetrate well around the lesion, for it will relieve the surrounding inflammation and lymphangitis. In none of the cases was there an occurrence of spurious carbuncles subsequently which is not infrequent after surgery.

Epitheliomas in Sebaceous Cysts.—H. D. Caylor (*Annals of Surgery,* July, 1925) finds that:

Sebaceous cysts can develop in almost any portion of the body covered by epidermis, the palms included. They are retention cysts caused apparently by obstruction of the duct of the gland and accumulation of the sebum. All sebaceous cysts should be removed, for they may become the site of a malignant tumor. Approximately 3.44 per cent. of the sebaceous cysts in this series eventually became malignant. The lesion should be excised if it is ulcerated, and excision is imperative if the lesion recurs. Obviously all sebaceous cysts should be examined carefully for malignant change. Heredity was apparently an etiological factor in the development of epitheliomas in the cysts studied since 58.33 per cent. of the patients with epitheliomas gave a family history of malignance, while only 13.83 per cent. of the patients with simple uncomplicated sebaceous cysts gave a personal or family history of malignancy. Local irritation, while it may be an item in causing the development of malignant change, was not the most important factor.

Skin Tests, Asthma and Idiosyncrasy.—The following conclusions are drawn by F. G. Chandler (*Lancet,* June 6, 1925):

1. Group testing is efficient if the solutions employed are not too weak.

2. Proteins, it appears, will keep active in solution with 0.25 per cent. or 0.5 per cent. carbolic for at least two years, and this is a convenient method of keeping test group solutions.

3. The best method of preparing proteins depends upon the use to be made of them. As a general rule it may be said that the powder form is the most satisfactory. Often, however, the powders become very insoluble, in which case precipitation and immediate resolution is the best method.

4. It appears that many of the substances used can be boiled without altering their activity.

5. The existence of a dermal reaction, even a well marked one, must not be taken as proof positive of an etiological relationship between the substance producing this reaction and the symptoms of the patient, though it must not be ignored without consideration.

6. It is too early to dogmatize about the therapeutic application of the discovery of an idiosyncrasy.

7. To sit down to a case of some obscure malady with a miscellany of test proteins is not likely to yield any useful result, but to investigate any case of strongly suspected idiosyncrasy, particularly from the point of view of desensitization, will yield valuable material for the study of idiosyncrasy and its treatment.

Radium Treatment of Vascular Nevi.—Charles Mallory Williams and Eugene F. Taub (*Archives of Pediatrics,* June, 1925) asserts that radium is the best single agent in the treatment of vascular nevi. Such types of nevi as the flat, superficial vascular nevi, level with the skin and which cannot be made to disappear on pressure, and the flat, deeply infiltrating vascular nevi, level with the skin, that usually cannot be made to disappear on pressure, are best treated with either the Kromayer light under pressure or the actual cautery point. The raised, soft vascular nevi, which are cavernous angiomata and are sometimes pulsatile and erectile, and the deep subcutaneous and submucous angiomatous tumors, are indications for either the cautery or surgical excision. Radium, though time consuming and expensive, may be employed before surgery mav be deemed advisable. Furthermore, it is possible to apply it in locations, as for example, eyelid, lip, etc., where other methods are contraindicated. Bleeding is not a contraindication to radium, in fact it may be promptly checked and the healing of ulcers (not infected) may be promoted. Adults respond poorly to radiation, comparatively speaking—lesions which in infancy would have rapidly melted away require tremendous dosage before being favorably influenced.

FRACTURES

Elbow Fractures and Dislocations.—I. E. Siris (*Surgery, Gynecology and Obstetrics,* May, 1925) summarizes his findings as follows:

Children have excellent reparative powers in fractures.

Perfect anatomical approximation of the fragments is not always essential for functional recovery. Displacement and overriding of fragments will often result in a good functional limb and complete restoration of the bony contour.

The best results are obtained by immediate reduction under an anesthetic with the aid of the fluoroscope.

Partial immobilization with adhesive and early active motion will reduce swelling, increase muscular tonicity, and prevent muscular spasm, exuberant callus, Volkmann's ischemic paralysis and myositis ossificans.

Passive motion with or without an anesthetic and active massage retards progress.

Musculospiral and ulnar paralysis accompanying and following fractures about the elbow is not always permanent.

Myositis ossificans will disappear with the discontinuation of trauma to the brachialis anticus.

Open operations in children are not indicated as good functional limbs will follow displaced fragments and infections are very prone to follow open operations.

Compound fractures are best treated by débridement, Carrel-Dakin sterilization, suspension in flexion by adhesive or in a flexed Thomas splint, to be followed by secondary suture or granulation with the institution of early active motion.

Active Motion in the Treatment of Fractures.—J. L. Yates and G. W. Stevens (*Annals of Surgery,* October, 1925) give reasons to show why bone repair occurs more promptly and advantageously, if active motions are employed. Also evidence to prove that cooperation with the natural reparative processes leads to earlier healing and more complete functional recoveries than are obtainable by the orthodox procedures wherein immobilization is enforced. Progress made in treatment is commensurate not only with reductions in mortality rates, but also with restrictions in durations of immediate and in extent of ultimate disabilities. Advances are noticeable when therapeutic procedures coop-

erate with natural processes which include resistance, defense, growth and repair. Treatment of fractures, so as to cooperate with Nature's methods of healing is the one way to obtain better results. Active motion is a constant factor in recovery and no recovery is complete until unrestricted active motion is possible. The earlier active motion is instituted the more prompt and complete are recoveries, provided a development of deformities is prevented during the healing process. Methods of treating fractures should be designed to interfere the least with general activities and to permit the earliest resumption of active motion by the structures involved in the injury.

Fractures and Their Roentgenological Interpretation.—R. H. Stevens (*International Journal of Medicine and Surgery,* January, 1925) discusses in detail the following points:

The bones of the hands and feet show a considerable number of anomalous variations and many of them suggest fractures, so that in case of injury it is an easy matter to make a mistake in interpretation, if one is not fully informed of the possible developments. There are, of course, anomalies of the spine, ribs, and other bones.

Sesamoid bones vary much in number and appearance and occasionally confuse the uninitiated.

The normal development and position of ossification centres, of course, must be constantly in mind in diagnosing injuries in persons below twenty-one years of age.

In the skull we have the greatest difficulties because of its globular form and its variable markings from channels of bloodvessels in its diploë and inner surfaces. Unless röntgenograms are taken in many different positions, the central beam of rays may not fall in such a manner upon a fissure fracture as to demonstrate it upon the plate. It is often difficult to differentiate the latter from the normal channels of bloodvessels. The slightest motion of the head during exposure to the rays will cause sufficient blurring of the plate to obliterate tracings of fine cracks and fissures.

Pathology of bone often results in fracture without much or any violence, and this condition must be differentiated from fractures of normal bones.

Old fractures must be differentiated from recent fractures to protect employers from unjust damages. Where, when, and to what extent we may expect callus, is of great importance.

Fractures of the Radius.—S. W. Boorstein (*American Journal of Surgery,* March, 1925) concludes as follows:

1. Reduction of a fracture of the lower end of the radius is a serious operation and should be carefully performed, and not delegated to the youngest intern or appropriated by the inexperienced general practitioner.

2. The typical deformity is that the lower end of the radius is displaced in four ways, viz., backwards, upwards, to the radial side, and rotated backwards, and the styloid process of the ulna is usually broken off.

3. To obtain a good result two things are of paramount importance: correction of the displacement and early mobilization.

4. The best methods of reduction are Jones' and Cotton's.

5. It is best to begin massage and active exercises on the third day.

6. Stiffness of the fingers should be avoided by early use.

7. Some slight deformity may remain, especially widening of the radius.

8. Some permanent shortening of the radius may result from condensation of the tissue of the lower fragment where the upper fragment is impacted into the lower.

9. Shoulder pain is due to the impaction force and should be avoided by early baking, massage and use of the shoulder and hand.

10. A roentgenogram should be taken before and immediately after reduction, and at short intervals during the course of treatment. The patient should not be discharged without a final roentgenray examination.

End Results of Fixed Traction in Fractures.—H. W. Carr and J. E. M. Thomson (*Journal of Bone and Joint Surgery,* July, 1925) advocate from their results that leg fractures be treated by having the traction imbedded into the cast. After treating in all one hundred cases of fracture with fixed traction without a single non union, with less than one inch of shortening in any case, and in most cases good anatomic as well as functional results, we feel convinced that this method has proved to be superior to any other. There are those who still maintain that a certain amount of motion between fracture fragments is desirable and that the formation of callus and the healing of fractures is promoted thereby. It is our opinion that this is bad teaching, for the reason that in the best methods of splinting we now know, and especially as usually employed, undue mobility of the parts is the common cause of failure to get good results.

Joint stiffness from disuse after the fracture has healed can readily be overcome by physiotherapy. In those cases where the fracture is in or near a joint, return of function is much greater if the parts are protected from irritation and further trauma than when ineffective fixation is employed or too early movement is tried. The pathological changes that take place in an injured joint with a traumatic inflmmation are similar to those of any other acute infectious arthritis and they respond similarly to absolute rest. By this procedure healing of the diseased surface is hastened and joint damage is minimized. If there is constant movement of such joints, productive or destructive changes occur which are irreparable.

What is to be remembered is that full length and correct line having been obtained, both the length and the position are to be maintained by the cast and the fixed traction.

After the first few days the traction may be said to cease functioning as traction and to serve from that time on simply as a factor in immobilization. This is true for the reason that there is a minimum of motion of the fracture fragments. There is little or no muscle spasm, and the plaster cast and the moleskin adhesive straps prove to be what splints so commonly are not—a true fixed dressing—with immobilization in correct position an accomplished fact.

GYNECOLOGY

Improvements in the Operative Treatment of Uterine Retrodisplacement.—H. S. Crossen (*American Journal of Obstetrics and Gynecology,* September, 1925) states that a considerable proportion of patients with retrodisplacement—particularly before childbearing and after the menopause—have no pelvic symptoms and need no treatment for the displacement. Further, in some of the patients who do have pelvic symptoms, these symptoms are due to some entirely separate lesion, which alone requires correction. Of the patients having disability due definitely to the retrodisplacement, some may be relieved completely by nonoperative treatment. In the cases actually requiring operation, Alexander's operation has proved a failure because it does not correct associated conditions to which the discomforts and disability are mainly due. Most patients have complications requiring intraperitoneal treatment. In cases with adnexa intact and the tissues freely movable, the author deems the following methods effective in the order named: Transplantation of the round ligaments into the abdominal wall by a modified Gilliam technique; posterior implantation of the round ligaments (Webster-Baldy operation); intraperitoneal folding of the round ligaments. In cases in which the tube and ovary of one side have been removed, the best procedure is to fold the round ligament back over the pedicle on the affected side and to shorten the opposite round ligament by reefing, folding over the uterus or drawing backward through the broad ligament. In cases with marked relaxation of the uterosacral tissues and prolapse of the cervix the author, in addition to shortening the round ligaments, resorts to Young's procedure of shortening the uterosacral tissues by sutures sufficiently to lift the cervix into the posterior half of the pelvis. In cases with the pelvic tissues infiltrated and stiffened, the method to be chosen for forward fastening of the corpus uteri depends on the extent of fixation of the tissues. Where the tissues are still sufficiently movable, a short loop of each round ligament may be brought into the abdominal wall and securely fastened there. Round ligament suturing over the top of the uterus gives a forward fastening which is fairly good. Where the broad ligament tissues are so infiltrated that the fundus cannot be brought well forward, partial replacement is best secured by suturing the infiltrated round ligaments and adjacent portions of the broad ligaments to the abdominal wall.

Pelvic Lesions as a Factor in Chronic Cystic Mastitis.—C. Jeff Miller (*American Journal of Obstetrics and Gynecology,* September, 1925) asserts that not only is pelvic disease very often the cause of chronic cystic mastitis, particularly in young women, but also very frequently the condition will disappear without local treatment if the pelvic disorder be identified and corrected. He now declines to pass upon the character of any breast lesion in a young woman without first reviewing her menstrual history and

making a thorough pelvic examination when indicated. Some fifty per cent. of patients with benign breast lesions show also fibroid growth, definite adnexal pathological states, or irregularities of menstruation, particularly those associated with the stigmata of developmental errors. As typical illustrations of the practical bearing of this relationship, the author refers to his recent reexamination of four patients subjected to myomectomy two or more years ago in whom fibroids or chronic hyperplasias of the uterus associated with the pelvic growth; these conditions had uniformly disappeared in a few months after operation. Fifteen cases of fibroids or chronic hyperplasias of the uterus associated with excessive menstruation were all completely relieved of annoying breast symptoms upon treatment with radium. In numerous instances the correction of displacements, the cure of adnexal disease, the relief of menstrual irregularities and even the repair of lacerations have resulted in a striking cure of the breast condition, often without even the removal of the affected area. Nevertheless, definite, circumscribed masses or single, isolated cysts in the breast of young women should be removed. Pain is an almost constant accompaniment in the benign breast conditions; where pain is a symptom of cancer the process is ordinarily so far advanced that the clinical manifestations are easy to recognize. Benign growths vary in size and consistency.

Uterine Prolapse and Rectocele.—J. Homans (*Annals of Surgery,* September, 1925, advocates treatment of this complication by closure of the pouch of Douglas, on the following grounds. Closure of the pouch may be a difficult but not of itself a dangerous procedure. It not only closes with some effectiveness the neck of the hernial sac but leaves the uterus interposed across the superior strait of the pelvis, the fundus anterior and the cervix posterior, in such a position that pressure from above is transmitted forward toward the pubis and no longer tends to push the cervix down into the axis of the vagina.

And though the procedure, as here reported, has been used without the aid of very carefully determined indications, it may apparently be relied upon, in association with a thorough vaginal repair, to cure a rather high percentage of prolapse and procidentia, and is useful especially when the posterior rather than the anterior vaginal wall is chiefly relaxed; when the uterus is of fair or good size and when the abdominal walls is so relaxed as to offer a poor support for any form of fixation.

Conical Resection of the Uterus.—J. N. Jackson (*Surgery, Gynecology and Obstetrics,* September, 1925), offers the following operative technic:

The abdomen is opened by the usual midline suprapubic incision. If there is no other intraabdominal complication a fairly short incision is sufficient. The fundus is grasped with a double volsellum and drawn up. In cases in which this operation is particularly indicated the uterus presents well above the abdominal wall. The peritoneum is closed around the uterus, the cervix being caught just above the bladder reflection in front and likewise low down on the cervix behind. The suture is carried on to complete closure of the entire peritoneal incision. The peritoneal cavity is thus opened only momentarily, and the remaining work is completed extraperitoneally. The tubes and ovaries are just below the peritoneal suture. Each cornu of uterus is grasped with other volsella to hold the organ taut. A conical resection of the body of the uterus is made well down to the cervix in front and behind, the cutting being done entirely outside the mucosa until the canal is divided at the lowest level. In making this excision the cut is bevelled. The bleeding is remarkably slight. A few vessels on the cut surface may require ligation. A suture ligature which does not slip is best. A few mattress sutures may be used across the bottom of the bevelled flaps to control bleeding further and to approximate the lower portion of the groove. The anterior and posterior edges of the uterine flaps are sutured together from cornu to cornu, usually with an interlocking suture to further suppress oozing. We now have two finger-like round ligaments on each side with the cervical canal entirely closed over. Before this suturing the mucosal canal is sterilized either with carbolic acid or better with the actual cautery tip. An undermining incision just above the rectus fascia is made on either side and a puncture is made through fascia and muscle about one inch outside the median incision. This puncture is made large enough to permit delivery of the tonguelike flaps without strangulation. The delivery of the flaps is usually made with a small double tenaculum passed from without inward, the tip of the ligament being grasped and pulled through to the top, as in a round ligament operation. The remainder of the original abdominal incision is closed in the usual manner, the two uterine flaps being brought over and sutured together in the midline and to the rectus fascia. The uterus is thus held up firmly as by ice tongs and cannot get loose. The skin incision is closed with a small drainage of rubber dam to provide for possible oozing.

This operation brings the cervix up to the level of the abdominal wall and effectively takes out the pelvic slack. It is well to remember that the flaps above the fascia will present a small continuous mass which might be mistaken for a hernia by a patient inclined to be uneasy. This can be prevented by proper explanation. The uterine and ovarian vessels are not ligated and the ovaries are left with a normal circulation. The patient is sterilized. Occasionally for short periods of time there may be a slight menstrual flow of blood from the mucosa of the cervical canal unless this is destroyed by cautery. This possibility should likewise be explained.

Ovarian Dermoids.—J. D. Koucky (*Annals of Surgery,* April, 1925) finds from his series of cases that patients with ovarian dermoids usually come to the surgeon during the fourth and fifth decades of life. Unilateral dermoids do not markedly interfere with childbearing; if the dermoids are bilateral, this function is definitely reduced. The symptoms of ovarian dermoid are due chiefly to pressure on surrounding organs, and to complications. The menstrual flow, in spite of the marked distortion and destruction of the ovaries, is increased rather than diminished. Röntgenological examination, made in a small number of cases, revealed pelvic shadows in half of them.

Congenital Absence of Uterus.—L. R. Wharton (*Surgery, Gynecology and Obstetrics,* January, 1925) advises that in making a clinical study of a case of congenital abnormality of the uterus, one must bear in mind that the genito-urinary organs have a common origin, and in their development are inseparably associated. Such malformations must therefore, be studied from the viewpoint of the genito-urinary system as a whole. Malformations of the uterus are occasionally associated with developmental defects of organs not in the genitourinary system; such defects have been found most commonly in the abdominal wall, the bony pelvis and the structures derived from the cloaca, *i. e.*, the rectum anus and bladder. A satisfactory explanation of these associations has not yet been made. The experimental work of Hertwig and Stockard demonstrates that congenital defects have their incipiency farther back in embyronic life than we have heretofore supposed.

PEDIATRICS

Malnutrition in Infants with Cleft Palate.—J. A. Foote (*American Journal of Diseases of Children,* September 1925) states that infants with cleft palate are frequently below normal nutritional standards during the first year of life. This condition of malnutrition is accompanied, if not caused, by a diminished fluid intake as compared with the normal infant of the same age. Diminished negative pressure in the mouth during the act of sucking, caused by the entrance of air from the nasal cavity through the palate cleft, causes infants with cleft palate to work at a mechanical disadvantage. An obturator closing off the nostrils increases the negative pressure within the mouth in certain selected cases, and enables the infant to suck to greater advantage and to take a larger quantity of food in a given time. To accomplish this the author used a simple strip of dental rubber dam about two inches wide and four inches long, to which was attached tapes at each side, and the tapes tied so that the rubber was stretched with sufficient tightness to block off the nostrils, the lower end of the rubber dam lying over the lip and the nipple. This effectually excludes the air. Air for respiration is given by gently lifting the upper edge over the nose, between sucking contractions.

Blanching Test in Scarlet Fever: Use of a Specific Streptococcus Antiserum.—Samuel J. Levin and John J. Parsons (*American Journal of Diseases of Children,* August 1925) carried out some experiments with the Schultz-Charlton blanching test in scarlet fever, using the globulin portion of horse serum prepared by a commercial antitoxin manufacturer for experimental purposes. This serum was prepared by injecting horses intravenously with the whole cultures of hemolytic streptococci obtained from scarlet fever

cases and subcutaneously with filtrate (toxin) of these organisms. The test was carried out by injecting one c. c. of the globulin solution intradermally in fifteen patients who were frankly ill with scarlet fever and showing a well marked eruption, usually within the first forty-eight hours of the eruption. In all cases, including three done at seventy-two hours and one at ninety-six hours, blanching was secured by the antiserum.

The blanched areas were from five to ten cm. in diameter, slightly irregular in shape and usually presented many radiating lines of blanching, extending to the surrounding rash for five to eight cm. The areas of blanching appeared in from four to six hours. In seven cases a two zone reaction appeared. This consisted of a reddened area in the centre of the blanched area, varying in size from 0.5 to 5 cm., which appeared earlier than the blanched area and usually disappeared before the rash faded.

The results of this small series would seem to indicate that the specific antiserum used possesses definite antibodies for scarlet fever. Enough data on the therapeutic use of this antiserum have not been collected to warrant a report on this aspect. On account of the greater difficulty in obtaining normal or convalescent serum for the blanching test, it appears that a specific antiserum would fill a practical need in the diagnosis of scarlet fever. In the fifteen cases in which it was tried, the antiserum mentioned above was effective in producing the blanching phenomenon. This antiserum was not effective in blanching the eruption of two cases of erysipelas and of two cases of scarlatiniform eruption on an anaphylactic basis. In three cases the authors were unable to blanch the rash of scarlet fever by using diphtheria antitoxin.

Rheumatic Infection in Childhood.—Vincent Coates and R. E. Thomas (*Lancet,* August 15, 1925) studied forty-four cases of rheumatic infection in children and they come to the conclusion that this infection in elementary school children is not a poverty disease, but that it is extremely prevalent among such children. The potency of heredity and low lying locality is emphasized. Subcutaneous nodules were demonstrated in thirty-five out of forty-four cases (79.5 per cent.), and are significant of an active rheumatic focus, as shown by their association with symptoms and their absence in three cases of stationary mechanical carditis formerly rheumatic. Thus their presence not only crystallizes an otherwise nebulous diagnosis, but indicates the necessity of continuation of treatment, particularly in nervous children and in those with unsatisfactory cardiac sounds.

The proliferation of the lining endothelial cells of arterioles and perivascular collections of histiocytes, is such as obtains in response to the virus of rheumatic fever, both in the endocardium and pericardium. It would appear, therefore, not improbable that these nodules are but pocket editions of the large subcutaneous nodes occurring in acute rheumatic fever and are analogous to the submiliary nodules of Aschoff.

In the treatment it has been found that satisfactory results are more easily obtained by the exhibition of small doses of thyroid or iodine in addition to salicylates, alkalies, and arsenic. This treatment was adopted on the presumption that smouldering infections tax the thyroid gland. Test, exclusion from school ,and avoidance of wet were enforced where necessary.

Vaccine Therapy the Method of Choice in the Treatment of Whooping Cough.—After thirteen years' observation and considering the fact that Charles James Bloom (*Archives of Pediatrics,* August, 1925) has followed many plans of treatment and different combinations of vaccines, the therapy advocated for the management of whooping cough is found to be the most efficacious in all respects. As a preventive in less than one per cent. of those vaccinated has whooping cough developed up to this time. And, finally, the death rate of zero may convert those who still doubt the value of the vaccine therapy in whooping cough. The author's series comprise 841 cases with accurate records, at almost two and one half times this number were followed. Of 383 patients immunized, only four cases of whooping cough developed, even though seventy per cent. of these patients were exposed to infection.

The following routine is now followed in the prophylactic cases: 1. The mixed vaccine, each cubic centimetre containing 8,500,000,000 bacteria of which the pertussis bacilli number 5,000,000,000 and the influenza bacillus 3,500,000,000, is used. 2. This vaccine is given within ten days after it has been prepared. This is very important. 3. One cubic centimetre is given on alternate days for three doses, then one c. c. every second day, if the complement fixation test justifies it. 4. In cases of marasmus, congenital lues, bronchial asthma, convalescence, and in infants under one month of age, half the specified amount should be given.

In the curative cases, 1, always use a fresh vaccine—not exceeding one month; within ten days preferred. 2. The initial dose should be a maximum dose, and subsequent doses should be of the same amount providing there is no marked reaction; then a reduction of 0.25 c. c. is made in the succeeding dose. 3. Give injections on alternate days, until one of the more pronounced symptoms (number of coughing spells; intensive coughing spells; cyanosis, vomiting, loss of appetite and restlessness) are on the wane. If cyanosis is marked, associated with or without the loss of consciousness, adrenalin chlorid is added in amounts proportionate to age. 4. Do not limit the number of doses—give as many as are indicated in the individual case. 5. Anaphylaxis was never seen; reactions limited in number with fever seldom exceeding 102° F. lasted but a few hours. The local reaction is trivial. 6. Usually no drugs are given when vaccine therapy is used. Sedatives may be used to facilitate sleep, but in all cases maximum amounts of the various iodids are given when the vaccine is discontinued. The average was four doses for each case treated. The presence of both leucocytosis and lymphocytosis means a diagnosis of pertussis.

Mongolian Imbecility as an Anthropological Problem.—Charles Herman (*Archives of Pediatrics,* August, 1925) states that recessive unit factors may reappear in a descendant, after remaining latent or concealed for many generations. Defective embryos are the least likely to mature. This is probably due to the presence of the socalled lethal factors which cause disintegration of the fertilized ovum. Other congenital anomalies are often present in mongolian imbeciles. Many of these are definitely known to be due to the presence of recessive unit factors. There is probably an infusion of mongolian blood in a certain percentage of Europeans. There are many points of resemblance between mongolian imbeciles and racial mongols. There are also a few differences. There are several points of resemblance between mongolian imbeciles and the anthropoid apes, but there does not appear to be conclusive evidence that they are more closely related to the orang than to the other anthropoids. Both the anthropoid and the mongolian characteristics or unit factors must have been present in the parent trunk from which the human and the anthropoid branches were derived. If we assume that mongolian imbecility represents a reversion to a primitive type, we have an explanation of certain anthropoid and mongolian characteristics.

Bone Marrow Studies in Infants.—Eugen Kramár and Valerie Hensch (*Monatsschrift für Kinderheilkunde,* August, 1925) say that with the proper technic and complete asepsis the puncture of the bone marrow in the living infant is a harmless procedure.

Normally the bone marrow of infants shows a greater number of granulated cells (promyelocytes, myelocytes, juvenile, coarsely and finely granulated cells) than lymphoid elements. The normal bone marrow picture is leukocytic (average sixty-one per cent. leucocytes, twenty-five per cent. lymphocytes). The proportion of the juvenile, coarsely granular and finely granular blood cells is different in the bone marrow than in the blood, the coarsely granular cell predominating. The basophiles are few in number (under one per cent.) in the bone marrow. The number of eosinophiles is generally one to three per cent. Of the lymphoid cells, the lymphocytes predominate. Among one hundred leucocytes, there is an average of five to ten nucleated red blood cells, and these are exceedingly numerous in syphilis (twenty-four to forty-seven per cent.).

In infants suffering from an exudative diathesis, there is usually a pronounced bone marrow eosinophilia (eight to nine per cent.), frequently even in those cases where there is no eosinophilia in the blood. In the slight cases of rachitis a mixed bone marrow picture, but in the severe, uncomplicated cases a pronounced lymphatic bone marrow picture is characteristic (average thirty-four per cent. leucocytes, fifty-four per cent. lymphocytes). Complications may produce changes in the picture. Pertussis also seems to be associated with a bone marrow lymphocytosis. Those diseases that rather produce a leucocytosis in the blood picture, show no striking changes as a result of the normal leucocytic type of the bone marrow.

Medicolegal Notes.

INSURANCE COMPANY JUDGE OF ADVISABILITY OF ISSUING LIFE POLICY

In an action on a life policy, defended by the insurance company on the ground of material misrepresentations in the application regarding health, the application containing a provision by which the applicant agreed to forfeit right of recovery if any representation in the application should be false if made with intent to deceive, or if it materially affected either the acceptance of the risk or the hazard assumed, the New York Appellate Division held, Denler v. Continental Casualty Co., 209 N. Y. Supp. 629, that it was entirely optional with the company whether or not it accepted the application and issued the policy, and therefore a charge that it could not relieve itself from liability by merely saying it would refuse the risk, but only if it would have been justified in refusing because of the ailment, was error.

HELD THAT MALPRACTICE CASE CANNOT BE BASED ON OPINIONS THAT DIFFERENT TREATMENT SHOULD HAVE BEEN FOLLOWED

In an action against three physicians for malpractice in the treatment of a fractured wrist in which infection had set in, plaintiff's expert witnesses said that large incisions should have been made in the arm when the infection appeared. Defendant's experts considered the draining of the wound, as was done, the proper treatment. All admitted that infection is likely to arise in any case; and that it can come from a condition of the blood as well as from an outside source.

The trial court having directed a verdict in favor of one of the defendants, the case came before the New Jersey Supreme Court on plaintiff's rule to show cause. That court held, Granaldi v. Zeglio, 129 Atl. 475, that the trial court ruled properly in granting defendant's motion for a directed verdict. The court said, in part: "A physician is not a guarantor without express contract of the good effects of his treatment, and he only undertakes to do what can ordinarily be done under similar circumstances.

"The testimony showed that treatment of an infected arm by draining as was done in the present case was a well-recognized and standard form of treatment. The fact that the plaintiff introduced evidence of physicians and surgeons that they would have made incisions in the arm which would have laid it open from the wrist to elbow is not evidence of malpractice. Surgeons of influence frequently differ in their opinions as to the treatment to be used in a given case. To permit a jury to pass upon the question of malpractice because testimony is given by physicians that they would have used a different treatment from the one prescribed or followed would be to make a physician or surgeon a guarantor of the success of his treatment in every case. If he fails to restore his patient, he must face a lawsuit with its accompanying annoyance and expenses. If the plaintiff's position be sound, a jury must pass upon the question whether the treatment given was correct or not. As the plaintiff did not respond to the treatment given and his arm became restored to its condition prior to the fracture, it could be expected that a jury would reach the conclusion that some other treatment of the condition which arose should have been applied. The result would be to return a verdict for the plaintiff, notwithstanding the same infection might have followed the other kind of treatment. If such were the law, there would be few physicians and surgeons who would undertake to treat a case. For every failure to effect a cure would lay the basis for a lawsuit.

"It takes more than the opinion of one or more physicians or surgeons that the treatment followed in a given case should have been different to lay a foundation for malpractice. . . . . A case of malpractice cannot be proven by the testimony of a few physicians or surgeons that they would have used some other treatment than the one used, in the absence of testimony from which it may be inferred that the defendant failed to give to the case that skill and care ordinarily possessed and exercised by others in the profession."

ADMISSION OF EXPERT TESTIMONY

In a personal injury action error was assigned because of the admission of expert testimony of a chiropractor on the ground that though he was not a licensed physician he was permitted to testify as an expert and to give the result of his examination of the plaintiff, and also to testify "as a layman" and to give in opinion evidence involving his physical condition. The witness had testified that he found in the plaintiff subluxation of the atlas; that this vertebra (subluxated) pressed upon the nerves which lead to the brain, the face and the skull. He was not asked whether in his opinion the condition he found might or could have been caused by a fall. The Missouri Supreme Court held, Meyers v. Wells, 273 S. W. 110, that a person who has made a special study of the human spine, followed by several years of experience in attempting to adjust "subluxation" of vertebræ, has shown such special knowledge of that subject as qualifies him to testify as to the condition or relative position of a vertebra found upon a direct physical examination. In that particular he has acquired, by technical training and practical experience, special knowledge not shared by men in general.

The testimony of a nerve specialist that a concussion of the brain, caused by a fall, so as to render the patient unconscious for 10 or 12 days could have caused a condition of the plaintiff which he testified he found on a physical examination, was held admissible.

DEATH FROM EXPOSURE IN REFRIGERATOR HELD COMPENSABLE

The New York Appellate Division holds, Lerner v. Rump Bros., 212 App. Div. 747, 209 N. Y. Supp. 698, that the unaccustomed exposure of an outside salesman for ten minutes in a refrigerator when called upon to show a customer some merchandise, resulting in a severe cold, which, according to medical proofs, culminated in his disability and death, was compensable as an accidental injury in the course of his employment, within the Workmen's Compensation Act.

HUSBAND ENTITLED TO RECOVER MEDICAL EXPENSES FOR INJURED WIFE

The New Jersey Supreme Court holds, Lanning v. Trenton etc., Traction Corp., 130 Atl. 444, that a verdict for a wife suing for personal injuries sustained by her, and a verdict of no cause of action as to her husband's claim for the expenses incurred by him in the treatment of her injuries, and compensation for the loss of her services and society, were irreconcilable. The rendition of the medical services was not disputed, nor was the propriety of the charges made for such services challenged. If the traction company was responsible for injuries to the wife, it was held to follow that the husband was entitled to recover such moneys as he had expended in the treatment of her injuries, and also a reasonable compensation for the loss of her services and society.

The Future of Biological Investigation*

HORATIO B. WILLIAMS, Ph.D.
New York

In choosing a topic for these brief remarks it seemed to me most appropriate to select one which would permit me to touch lightly certain aspects of the educational problem which concerns us all. I wonder what your views are regarding the value of education. Perhaps in common with many you think most of its utilitarian values. I think the average person regards an education as a training which will fit him the better to perform his daily tasks and enable him the more easily to outstrip his fellows in the struggle for material success. It is true that education will do this, but is this all? What after all is this material success for which so many people give their best efforts? To the lower animals and, I fear, to many men material success means meeting the needs of the body for food and shelter for today so that its existence may be continued until tomorrow and so on in endless repetition until at last the law of the sequence is broken and the individual's struggle for continued existence is at an end. Rightly regarded, the main purpose of an education is not grossly utilitarian. The capacity to derive more than mere animal comfort from material success depends upon the development of those powers which it is the function of education to cultivate. From this viewpoint all education is good, all knowledge is a source of joy to its possessor, but for the cultivation of a serene outlook on life and its vicissitudes, for the maintenance of a sound balance and correct perspective the discipline of medicine seems fortunate.

During the early years of childhood our every need is anticipated and we receive constant care. Later we must learn to depend on our own efforts and so gradually this parental care must be relaxed so that we may learn self dependence. So in our education at first we are merely given facts to learn. How anyone came to know them as facts need not for the present trouble us. Eventually we must depart from this method, for in time we shall reach a stage when the answers to our questions are not to be found in books nor obtained from men, but must be obtained direct from Nature. Some of you, I hope most of you, have already begun to reach the stage of intellectual independence, but it has been our observation in the past that the medical student craves definite statements of fact such as he becomes accustomed to in his more elementary studies. In some branches of the work this craving can be gratified to a limited extent, but in the greater number of cases definite dogmatic statements would be as likely to mislead as not. The medical sciences are growing. Methods of investigation improve. Things which were regarded as facts of observation a few years ago are shown by more accurate measurements not to be so. Theories particularly are subject to change in the light of new knowledge. You will not infrequently find several theories presented to account for some biological process. The evidence for and against these will be given and the decision left to you. You may find the decision hard to make and wish your instructor would make it for you. This he must not do, for in the future as knowledge advances you must be prepared to make your own decisions, and this you can learn to do only by beginning. The work of the physician and surgeon calls for ability to assume individual responsibility and make quick decisions in matters of great moment. You must begin doing this in your training period. If all of the fundamental medical sciences were fully understood, if disease always manifested itself in a constant and definite way, if there were for each ailment a definite curative treatment or surgical procedure, the teaching would be easier, but I doubt whether the subject would make the same appeal it now does to the man of intellectual courage.

There was a time when men believed that all life processes were so essentially mysterious, so inextricably bound up with the "vital" forces supposed to be different from those obtaining in the world of nonliving things that any attempt to understand the mode of operation of the living organism must be doomed to disappointment from the beginning. The success which attended Harvey's investigations on the circulation of the blood is a brilliant example of the fruitfulness of common sense and correct mechanical ideas applied to a biological problem. I presume that Harvey's teleological reasonings would provoke a smile nowadays, but that is largely a habit of thought and manner of expression. The point to be emphasized is that instead of allowing himself to be awed into inaction by the great mystery of life he proposed attempting to apply to one of the mysteries the mechanical principles which hold in nonliving mechanisms—and he found that the plan worked.

*Address delivered at the opening exercises of the College of Physicians and Surgeons, Columbia University, on September 23, 1925.

Copyright, 1926, by A. R. Elliott Publishing Company.

In the early days of chemical inquiry those substances which were derived from the life processes of plants and animals were called "organic" chemicals and it was believed that they could be produced only by the activities of plant or animal organs. To this day we preserve a memorial of that stage of thought in that we denominate a large branch of chemistry "organic chemistry." When, less than a century ago, Woehler succeeded in preparing from inorganic chemicals urea, a substance hitherto known only as a product of animal metabolism, it was realized that there is no necessary reason to assume other than the usual laws of chemistry to account for the production of certain at least of the chemical substances associated with life processes. To enumerate all of the substances which are the natural product of plant or animal life that have now been synthesized by the chemist from nonliving materials would be no inconsiderable task.

Johannes Mueller, leading physiologist of the early part of the last century and teacher of DuBois-Reymond and Helmholtz, held the view that it would be impossible to measure the rate of transmission of the nervous impulse. He believed the processes of thought showed that transmission must be instantaneous. A few years later his own pupil, Helmholtz, measured the rate with simple contrivances and showed that in the sciatic nerve of the frog it is not only finite, but of the same order of magnitude as the speed of a not very fast railroad train.

With the discovery of oxygen and its relation to combustion it was not long before the suspicion was aroused that oxidation might have something to do with animal heat. The expired air was found to be richer in carbon dioxide and poorer in oxygen than the inspired. Men had become familiar with the steam engine as a means of converting the chemical energy of coal into mechanical work. Could it be the oxidation of foodstuffs or of body substances elaborated from the foodstuffs which furnished animal heat and caused muscular movements? I have not time to go into the history of this matter and shall pass over the fundamental researches of Voit and Pettenkofer to mention briefly the culmination of these investigations in the work of Atwater and Rosa with the respiration calorimeter. These investigators proved beyond peradventure that the law of conservation of energy extends to the animal body. They showed that the burning of a gram of foodstuff outside the body yields precisely the same amount of energy as its slow oxidation within the body.

One might continue multiplying instances of this kind, but those mentioned are sufficient in number, variety and importance to illustrate the point I wish to bring out. While it has not been proven that there are no special "vital" forces the greatest progress in understanding the activities of living things has invariably resulted from attempts to extend to the living organism those physical and chemical conceptions which have been found true in the nonliving world. The assumption of a mysterious "vital" agency not subject to investigation by the methods of physics and chemistry tends from the beginning to deaden thought and kill initiative. I have no quarrel with the man who feels that such human qualities as the sense of honor, of altruism, of patriotism are too refined to admit of explanation as conditioned reflexes. It is not necessary for our purpose to assume at the outset that *all* life processes are of a mechanistic nature controlled by the same laws as those which obtain in nonliving matter. Such an assumption in the present state of our knowledge would be quite as difficult to defend as the vitalistic hypothesis. All that seems requisite to put the mind in the proper attitude for investigation is to determine that we shall endeavor to ascertain how far we may explain and account for the phenomena of life in terms of the laws which have been found to apply to physical and chemical processes in the inanimate world.

In presuming to choose for the title of my address The Future of Investigation in Biology I had not the temerity to think of trying to predict what the future will or will not bring in the way of particular results or even how, precisely, the result of increasing our biological knowedge is to be obtained. It is rather my purpose to indicate in a general way what seems to be requisite in order that some such fundamental advance may be made in biology as was that which Newton made in mechanics when he was able to prove the validity of his extension of the law of falling bodies on the earth to bodies throughout all space as far as data are available. I presume everyone has heard the story of Newton and the apple which fell on his head. It is hardly necessary to say that it is apocryphal. The true history is less well known and as the essentials can be given in a few words and bear upon what follows I may be pardoned for a slight digression. It occurred to Newton that perhaps the attractive force which causes bodies near the earth to gravitate toward it might extend into space indefinitely and if so even as far as the moon, perhaps accounting for her retention in her orbit. He immediately made a calculation to determine how far a body would fall in a minute at the distance of the moon if its fall were due to the same force which attracts bodies at the earth's surface. He found that the distance per minute would be something over fifteen feet, whereas the actual deflection of the moon from the direction of the tangent to her orbit was about thirteen feet per minute. I fear many of us would have regarded that as a rather close approximation, but Newton found it so unsatisfactory that he at once abandoned the theory. Thirteen years later he was again led to consider this theory and became aware of a better determination of the value of the earth's mean radius which had been made since his first calculation. The value he had used in 1666 had led to a wrong estimate of the moon's distance. With the new value he obtained a correspondence between theory and measurement which proved satisfactory to him. So satisfactory has it since proved that with ever increasing accuracy of observation and with data available not alone from our own solar system but from distant double stars, Newton's generalization is found to fit the facts. Only within recent years and in the fields of light and electricity have facts been observed which seem to require some slight modification of the Newtonian mechanical conceptions. Biology today is in something like the state in which mechanics and astronomy were in the days of Hipparchus or Ptolemy. We are living in the age of the epicycles. Our greatest need is for some generalization which will reduce to order the tremendous chaos of observations we now have before us. The

material from which the generalization must come is the body of observed facts. To be able to generalize from these facts, however, it is necessary that someone shall be familiar with all the different types of observational data which may reveal something essential to the generalization. It will also be essential that we have a fair general knowledge of the basic principles of chemistry and physics and some facility in applied mathematics. At first sight this would seem to require an incredible amount of preparation. Probably it would in the present state of biological science. No great advance is ever made by the unaided effort of one man. Many contributed their share before Newton was able to take the step he did. Many have contributed already to biology, but the kind of contribution we need now is a summarizing of the data. We are all of us at present too close to the great mass of detailed observation to see its broader implications. We need not waste time regretting this. The work which has been done had to be done, or at least much of it had to be done and possibly much more of the same type of work will still have to be done before biology is ready for a simplifying generalization. The broader view which is denied to us will be the heritage of our successors. They cannot, must not spend their time delving into the great mass of details. Gradually, through the efforts of many workers the more essential phenomena will be separated from the incidental so that it will be possible for one individual to survey the field without devoting so much of his lifetime to the task as to leave no opportunity for that familiarity with the related sciences which is requisite before a generalization can be made. Meanwhile we should do our best to secure *reliable* data so that the "Newton of biology," to use Cuvier's expression, may not be baffled in his work as Newton was by attempting to use inaccurate information. I believe that one of the most urgent needs in biological work today is a study of this very matter of the reliability of conclusions drawn from biological experimentation.

In so far as biological phenomena rest on a physical or chemical basis, we may hope for assistance from the advances made in these sister sciences. We do not know what day an important discovery or generalization in chemistry or physics may permit the coordination and understanding of many seemingly unrelated biological phenomena. If we could learn to express our biological facts without the use of quite so much special terminology, it is even conceivable that men in other fields of science might contribute to its theoretical handling. I think we might well give attention to this matter of unnecessary technical terminology.

We may perhaps draw a lesson from one of the features which has characterized the development of chemistry in recent years. Although scientific chemistry dates from the introduction of quantitative methods, the application of mathematical analysis with a view to pushing chemical knowledge beyond the bounds of observation is comparatively recent. Thirty years ago chemistry might have been described as a nonmathematical science. To the man who has not at least an elementary knowledge of mathematical analysis modern chemistry is a closed book. In fact the application of mathematical methods promises to do as much for chemistry as it has done for physics. In most branches of biological work it is difficult at present to secure quantitative accuracy comparable with that attained by the pure chemist or physicist. Gradually as our methods improve it should be possible to investigate our results under the microscope of mathematical analysis. When this can be done we may begin to hope for the long awaited generalization which is to bring order out of chaos, reduce the size of our volumes and give us time for a broader outlook.

What should be the preparation of the biologist of the future? I can attempt to answer this question only in general terms. Medicine, in its practical aspects, is applied biology, and the preparation for its study will depend on the character of the biology of the time. It must of necessity be along rather definitely prescribed lines. For the student of pure biology or for the medical student who determines for the first time that he is to devote his life to investigation and teaching rather than to practice more latitude might be allowed. It seems to me most desirable that there should come into the biological sciences men of widely different training. There should be some who are trained as chemists, others trained as physicists with the usual mathematical equipment of the physicist. Still others should probably have much the type of training which most of our present day biologists have had, with perhaps somewhat more emphasis on precise quantitative methods.

The Causal Parasites of Cancer

J. JACKSON CLARKE, M.B. Lond., F.R.C.S.
London

Over a third of a century ago a view then new was taken of certain alien bodies that are easy to see with the ordinary microscope in many common typical human cancers. One group of these bodies had been called "cells of endogenous origin" in 1851, others had been looked on as degeneration products. In the new view one or both sets of these bodies were believed to be parasites; some observers thought them to be fungi, others sporozoa.

In 1892 it was affirmed that these alien bodies of cancer were of the same nature as the bodies called "psorosperms" in cystic ureteritis, and that in many human cancers and sarcomas their optical characters distinguished them from the tissue cells, and showed that they had a regular life cycle, which together with the distribution of the parasites in the several tumors left no doubt that they were the cause of the disease. (1)

During the past year it has been announced that filter passing parasites had been obtained from sarcomas of a fowl and of a mouse and from a human breast cancer; that these parasites had been grown in artificial cultures, and photographed on the dark ground and by ultraviolet rays, an elaborately constructed special microscope being required for this purpose. The parasites from all three sources resembled in form the protist which causes pleuropneumonia of cattle, and which was photographed in 1910, both in stained preparations and on the dark ground, the name Asterococcus mycoides being then given to this protist (2).

Can the relatively gigantic "cancer bodies" of 1890 be related to the filter passing cancer protists of 1925?

The answer to this question has very wide bearings on our comprehension of the full structural and functional potential of primitive forms of life; and the essence of this information is given by a simple experiment with the specific alien bodies of molluscum contagiosum.

Molluscum corpuscles when mature are the dense, more or less oval, bodies which are so strictly specific that diagnosis is made sure by their presence. Under a low power of the microscope they are easily manipulated with needles on a slide. The experiment consists in placing a ripe lesion, incised vertically, in a few drops of water in a watch glass in the way that I have described (3). On and after the fourth day active vital changes are always to be seen in some of the corpuscles. Taken together these active changes prove that the entire corpuscle is a protist entity, potentially equivalent to a sporange of a phycomycete.

The first changes that are visible are due to inception of water and are comparable to those seen in a sclerotic slime mould after it has been moistened with water: the dense half opaque substance of the corpuscles becomes clear and then lively and continuous circulation begins. This change usually begins in the middle of the corpuscles, then usually extends until it involves the whole corpuscle except an outer capsule and an internal framework when these structures are differentiated.

A section through the middle of a ripe lesion shows that the parasites constitute one third of the mass, and this fact considered with their distribution at different stages of evolution of the lesion leaves no doubt that the latter is caused by this parasite, which has been named plassomyxa contagiosa. In 1919 it was demonstrated that molluscum lesions ground up with sand and one or two c.c. of salt solution yielded by suction through a Berkefeld filter an infective fluid, which, injected into the skin of two volunteers, caused typical lesions, it exists in the lesion the causal parasite of molluscum is capable of being broken up into filterable fragments, some or all of which are viable; a fact which will not surprise anyone who has watched one of these parasites in a water culture when its protoplasm has begun to circulate and looks almost as clear and as fluid as water.

Many human cancers and sarcomas examined in fresh teasings in their own juice show abundant protist forms like some of the stages of the molluscum parasite as seen in water culture. This correspondence is also seen on comparing sections of cancers with water cultures of molluscum fixed when in full vital activity.

The alien bodies of cancer pass through endogenous stages which are homologous with exogenous (water culture) stages of plassomyxa contagiosa; or, in other words, the parasite of cancer probably belongs to the same genus as that of molluscum.

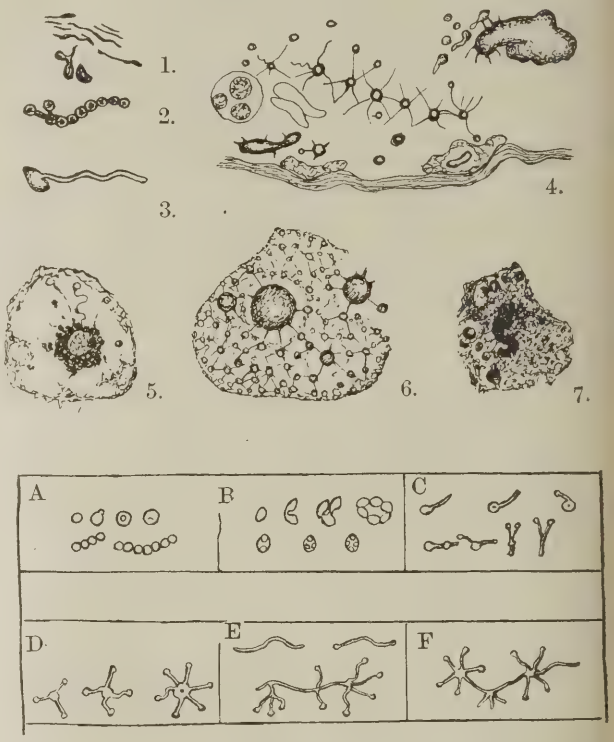

Fig 1.—1, 2 and 3 are from a choriocarcinoma, 4 to 7 from a mammary sarcoma. × 800 diameters, except 6 which is × 1600 diameters. 1, linear and irregular forms; 2, streptococcoid; 3, linear from oval; 4, parasites in a venule, above an irregular mass from which coccoid forms are separating, and below, linked asters; 5, a parasite inside the nucleus of a connective tissue cell, it is of asterococcoid type with a central vacuole, and is of a dense retiform composition, from a photograph; 6, parasite that has been like 5, but has migrated from nucleus into host cytoplasm and has withdrawn tentacles and imbibed water; its composition of smaller asters is plainly seen; 7, parasite from an intercellular space; from being like 5, a sort of molecular fusion has occurred with formation of a dense central nucleus from which by local refusion with portions of cytoplasm new asterococcoid amebulæ are in process of formation near the periphery; from a photograph.

A to F are different forms assumed by the causal parasite of pleuropneumonia of cattle, Asterococcus myeoides; × 5,000 diameters, after Borrel and others, 1910. A and B, coccoid forms; C, linear extensions from coccoid forms, also two forked forms; A, asters; B, linear and linear × asters; F, linked asters.

Proof of the existence of a filterable stage of the latter rendered it probable that a corresponding stage of the cancer parasite would be obtained by using a similar technic.

The finding and cultivating of a filterable protist obtained from sarcomas and from a human cancer in 1925 is complementary to the demonstration of protists in cancers and sarcomas in 1892 (4). In the adjacent figure are placed together a few parasitic elements as seen in a human choriocarcinoma and in a human mammary sarcoma with others copied in outline from a figure of a dark ground preparation of Asterococcus mycoides.

In human malignant disease many other structural varieties of the parasites occur; also in cultures four or five days old the asterococci fuse into masses some of which resemble mycelia.

NOTES

1. References to the accounts of L. Pfeiffer, Russell, Wickham, and others are given in the present writer's *Cancer, Sarcoma, and Other Morbid Growths Considered in Relation to the Sporozoa,* 1893; in the same book an account of the endogenous cycle of the cancer parasite is described, and it is shown how the cancerous process results from interaction of the host tissue and this cycle.

In 1906 in *Protozoa and Disease, Part II,* the parasitic causation of cancer is further illustrated as seen in an alveolar sarcoma of the breast, in a sarcoma of the testis, and in the infective granuloma of dogs. The share of phagocytosis in cancer and an account of a choriocarcinoma, and the part played by chromidia in the life of a mycetozoan are dealt with in *Protozoa and Disease,* Part IV, 1915; lastly, in *Protists and Disease,* 1922, details of the making of water cultures of molluscum corpuscles are given; and, based on broad comparison with mycetozoa and synchytrians the conclusion is stated that the causal parasites of molluscum and of cancer are nearly related to the genus Synchytrium, and hence are phycomycetes, not sporozoa.

2. The morphology of the causal microbe of pleuropneumonia of cattle is described in the *Annals of the Pasteur Institute,* 1910. Bordet in one paper, and Borrel, Dujardin-Beaumetz, Jeantet, and Jouan in another.

Other papers on the filterable virus of cancer by Gye and Barnard were published in *The Lancet* of July 18, 1925.

Besides forms such as are suggested in the illustration accompanying this paper Bordet and his colleagues found in cultures five or six days old that the parasites of pleuropneumonia sometimes coalesced forming myceliumlike masses, these they called involution forms. They resemble structures described by James Young in nutrient aerobic cultures of cancer and called by him sclerotia. (See *Edinburgh Med. Journ.,* July, 1924.)

3. The first suggestion that water cultures of molluscum afford a solution of many of the present problems in biopathology was made in the *Centralblatt f. Bakteriol.,* I. Feb. 28. A broad comparative study of molluscum, cancer, and other diseases, together with a practical study of protists such as slime moulds, synchytrians and kindred organisms is what I now recommend as being necessary to a right understanding of cancer.

4. The term microhenad is suggested (*Protists and Disease,* p. 108) for the filterable stage of a protist, a microhenad being a special sort of chromidioblast. When it lives in the epidermis the parasite of molluscum exists as aggregates of chromidial granules, such aggregates being capable of becoming encapsuled sporanges, or equivalent forms. Because a protist remains in a microhenad state when growing anaerobically in artificial culture some wrongly assume that it can have no other mode of existence; we may compare what happens when a mucor is grown anaerobically in the presence of glucose: it loses its ordinary stately habit and assumes its 'gemma' form, in which it grows like a yeast.

Plastic Surgery of the Nose*

A. G. BETTMAN, M.D.

Portland, Oregon

Plastic surgery is that surgery which aims to reconstruct or restore, as differentiated from surgery which primarily removes pathology. Both are necessary, are equally important and may be combined in one operation. Plastic surgery repairs defects and malformations, either congenital or acquired. It restores function and improves appearance. Plastic surgery has always in mind the ultimate cosmetic effect.

Plastic surgery does not involve new surgical principles but it demands the carrying out of these principles in great detail and with certain modifications of technic, to the end that newly imparted or improved beauty be not effaced by scar or other defect.

A patient having a collection of pus about the face applies for treatment. The indications are to drain freely. The surgeon makes an incision in the most prominent dependent portion. But having in mind the cosmetic effect the incision is placed so that the resulting scar will be as inconspicuous as possible. The patient appreciates the difference.

Is a surgeon justified in removing a defect and improving the appearance of a patient when the lesion is not causing pain or jeopardizing life? Decidedly, yes. Let me cite a few examples.

A young woman whose upper and lower lips were greatly everted and which protruded markedly applied for treatment that her condition might be ameliorated. In spite of her light skin she frequently was called upon to deny African descent. The excess of tissue having been excised without leaving a visible scar she was much pleased with her improved appearance. She was not vain but was she not entitled to relief from her condition?

In a fight a man had quite a large section of the helix and lobe of his ear bitten out. Should this wound have been merely sutured or was the surgeon justified in rebuilding the lost portion and effacing the defect?

A man came recently asking for relief from his unsightly appearance. He said he was in an occupation in which he had to meet business men in the spirit of optimism. He declared himself an optimist; he looked a pessimist. He wanted to know if the downward droop of his mouth could be corrected and if the heavy folds of skin of the lower face and neck which interfered with the buttoning of his collar could be removed. He felt sure his success in his work was interfered with by his appearance. Who is there that would say that this man should not be relieved of his disabilities?

A woman asked for help; her sagging double chin quivered when she talked or shook her head. Whether those to whom she talked suppressed a smile when her flabby chin quivered or whether she imagined it is beside the point; her efficiency was much reduced. Since this impediment, together with the wrinkles about her eyes and cheeks have been removed her gait is lighter, her smile is ever present, her appearance is many years more youthful and, best of all, her confidence in herself is very greatly increased. Was the improvement worth the effort?

A young man whose ears, through lack of proper development of the antihelix, stood out from his head applied for correction of the condition. Through incisions in the back of the ears an antihelix was built

*Read before the Portland City and County Medical Society.

into each ear thus folding them back against the head where they belonged. The difference was very striking and the patient appreciated it.

Then there is the problem of tattooing. Should this be removed? I excised a small tattoo from the arm of a woman of fifty-five who had made repeated

Fig. 1.—Condition of lips before excision of excess tissue.

Fig. 2.—Appearance after healing. All scar is inside mouth where it cannot be seen.

efforts for forty years to find some one who could rid her of her blemish. Large areas are removed by tattooing again with tannic acid and then applying silver nitrate. This leaves a soft faintly scarred surface without design or color. When I tell you that one man's wife threatened to leave him if a newly affixed design was not removed you will understand the necessity for the medical profession doing this work.

I have in mind a woman who had not been out of her home for thirteen years because of the destruction of her nose by tuberculosis. Should this unfortunate be denied relief?

Examples could be continued but let these suffice for this time. There are none but will agree that great deformities justify correction. Then, I ask, what constitutes a great deformity? A blemish that seems small to one person will assume large proportions when situated on the body of another. Chamois skinlike patches of xanthoma may be ignored by a few individuals but most would rather be rid of them.

There have appeared recently quite a large number of moving pictures which were either based on, had for their theme, or contained characters having various deformities of the face and bringing out the point that correction of the deformity was of great, often vital importance, not only to the individual but also to his friends and associates. These pictures have all been very well attended and freely commented upon.

There is probably not a national magazine or newspaper of any consequence in the United States that has not had numerous articles dealing with various phases of plastic surgery. These articles have been eagerly read and freely discussed by our lay friends. The public reads these articles with great avidity.

What do these things mean? They mean that the public is interested in the subject of plastic, cosmetic and reconstructional surgery far more than some members of the medical profession are willing to admit.

What will be the consequences if reputable surgeons refuse these sufferers relief and if reputable physicians decry plastic and cosmetic surgery? There can be but one result and that is that charlatans will do the work and this sector of "no man's land" will be occupied by these irregulars.

Do not misunderstand me. I do not favor unnecessary surgery. To be justified surgery must benefit the patient in his or her health or appearance. Every operation asked for need not be done nor should the patient dictate the procedure. The surgeon must use his best judgment to produce the correct result in all plastic surgery, following the wishes of the patient in so far as it may be possible.

A man came in asking that his nose be placed straight on his face, instead of to the left, where he thought it was located. On examination I could find no deformity of his nose either in shape or position. However, I did find a large transverse scar on the upper lip just above the vermillion border from the median line, extending more than half an inch to the left. At the time of the injury he had not had surgical attention and the ridge limiting the lip sulcus had healed considerably to the left of its normal position so that while the ridge on the right came downward in the usual direction, that of the left pointed far to that side, its lower extremity, however, being somewhat to the right of the normal position. Therefore, it can be understood why this young man thought his nose was not in proper position. The columnella was not in the centre of the sulcus. Excision of the scar and restoring the border of the sulcus to its proper position corrected the seeming malposition of the nose.

Among my most grateful patients are many that have been treated by some plastic operation. They are more grateful than patients who have been snatched from an untimely death and they do not hesitate to express their appreciation.

Plastic surgery is not confined to the face but as suggested reaches all parts of the body, wherever

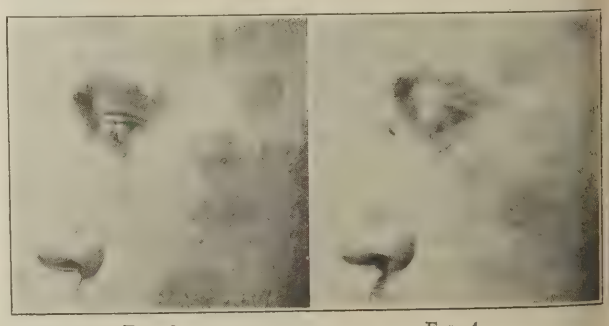

Fig. 3 Fig. 4

Fig. 3.—At age of ten, ten years ago, this patient was struck on the nose with a baseball.

Fig. 4.—Defect filled with celluloid as described.

deformities can be removed, or appearances improved.

A recent press notice detailed that a man had received an injury to his nose which necessitated amputation. I could picture in my mind no trauma which would justify such a radical procedure.

Every particle of tissue should be saved that possibly can be saved. Every little bit should be sutured as near as possible to the place from which it came and every effort should be made to conserve that which is left. By doing these things a later restoration can be done very much more easily and satisfactorily. Often a difficult piece of work might have been made more simple by a little forethought.

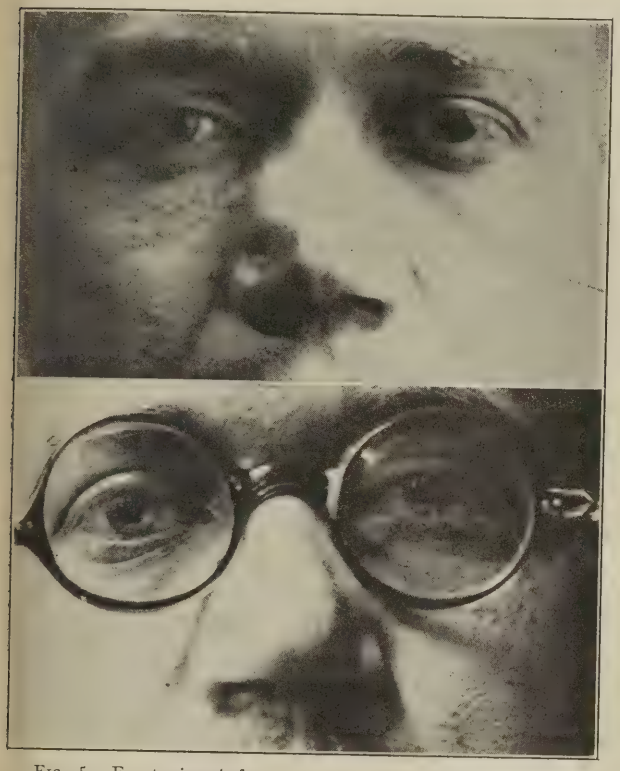

FIG. 5.—Front view before operation, same patient.
FIG. 6.—Improvement in his appearance was very marked. There are no external scars.

What is the proper procedure, when one meets an injury of the nose with loss of tissue, that cannot be repaired at once? Cleanse the wound well adding no additional trauma and preserve all bits of tissue, restore the shape of the nose as regards soft structures, bone and cartilage and maintain the restoration, and prevent shrinking of the loose edges. Thwart the contraction of the edges and their assuming false positions and shapes by suturing skin and mucous membrane together. When skin and mucous membrane are thus united very little, if any, scar tissue is formed, the edges unite without contracting and when the secondary operation is attempted the parts are found to have retained more nearly their normal shapes and positions.

The origin of plastic surgery goes back to the dim past in India and was developed as the result of the fight men and women were making, in those remote times, for the sanctity of their homes. Unfaithful husbands and wives were punished by having the tips of their noses amputated. The culprits soon learned that by reapplying the severed portion, their own or some one else's, it would often reunite restoring the organ. Subsequently members of the tilemaker's caste obtained wonderful results in constructing noses by the use of pedunculated flaps from the cheeks and later from the forehead. From this lowly beginning plastic operations of all parts of the body have developed.

In plastic surgery, as in other surgery, needless to say, asepsis is more important than antisepsis. Sepsis will spoil an otherwise admirable piece of work or produce unnecessarily wide scars. A minimum scar cannot be expected when even slight sepsis is present.

Especially important is it, at all times, to treat the tissues kindly. When the edges are handled with forceps or otherwise crushed wide scars are sure to result. When it is necessary to pull or hold the tissues sharp hooks may be used without injuring them.

Another thing that aids in the production of a small scar and an ideal cosmetic result is to see to it that hemostasis is complete. A small oozing will permit a droplet of blood to separate the wound edges. Use twenty-four drains frequently and especially in all cavities however small.

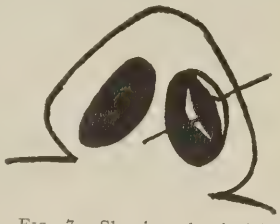

FIG. 7.—Showing the incision inside the nose retracted by silk threads.

Sutures must be accurately placed without tension. Tension that produces blanching will result in a slough, so relieve tension by the use of tension sutures tied over gauze. Tension may also be relieved by undercutting the skin. Do not hesitate to remove a suture that is not properly placed or that produces blanching.

In placing sutures do not approximate the wound edges. Bring the edges of the wound into exact apposition. Replace the thought approximation by the one exact apposition and the improved psychology will result in better technic and very much nicer looking scars. This applies not only to the face but to all parts of the body.

Sutures should be carefully tied so as to just bring the edges together, that is, so the edges just touch.

FIG. 8 FIG. 9

FIG. 8.—A nose deformed by an automobile accident.
FIG. 9.—The appearance after corrective operations.

When tied too tightly tissue must be removed and undue swelling results. When tied too loosely the distance between the edges must be bridged. When tied so that the edges just touch healing takes place

quickly, there is little or no reaction and the scar is very small.

I prefer horsehair for apposition sutures and these are removed early to prevent cross marking on the second, third or fourth day. For tension sutures fine or medium size silk worm tied over gauze is best. When the incisions are properly placed and carefully sutured the wound will leave no scar that can be readily seen. Careful, painstaking work is necessary to produce this result.

I usually apply dressings as follows: When placing sutures leave the ends of sutures at intervals long. When all are in place and tied a very small piece of rolled gauze is tied over the wound by tying the long ends. This dressing is sufficient and does away with bandages, adhesive plaster, collodion, etc., is easily removed, protects the wound and is inconspicuous.

Just a word regarding the removal of sutures. Care must be used so that the wound is not injured when the stitches are removed. It is not necessary to remove all the sutures at one time. Often I remove every other one or perhaps all except every third or fourth stitch. Horsehair is cut very readily without damage to the delicate edges while some of the substitutes require great force to cut.

If after completing a piece of work that is otherwise satisfactory the scar is too large or too prominent remove it later and substitute a smaller one.

I prefer to operate using novocaine (procaine) one to two per cent., with adrenalin hydrochloride solution one to one thousand, five minims to the ounce. Usually a hypodermic of morphine sulphate one sixth to one fourth grain with atropine sulphate one one hundred and fiftieth grain are given one half hour before beginning the operation. The patient remains quiet for several hours after operation and is then permitted to go home. Patients are seen usually every second day and recovery is uneventful.

Before beginning the reformation or rebuilding of a nose it must be definitely fixed in the operator's mind just what it is intended to accomplish, and exactly how the desired object is to be attained. The carrying out of the planned procedures to exactly the right extent gives the perfect result. One must possess a certain amount of imagination to be able to see the completed operation before the work is started. I find it of very great assistance to take photographs and make casts for study before operation as well as for records.

One must never operate while active disease is present. It is better to forego the operation than to attempt it while conditions are not favorable. A man under treatment for syphilis was referred to me for operation. The first time I saw him the anterior portion of the septum was gone and the columna still attached to the lip was free at the anterior extremity. The bridge of the nose was falling in and the deformity was not a pleasant one to look at. I refused to operate until he had had more treatment.

Six weeks later he again requested operation which was again refused. At this time a considerable area of mucous membrane over the alveolar process was denuded exposing a large portion of the superior maxilla which was necrotic and which when extruded must have left a large opening from the nose into the mouth. Wassermann at this time was still positive. Subsequently I was informed that his condition progressed from bad to worse. Had this man been operated upon the condition would have been made more disfiguring than before and the operative procedure may have been blamed for the destruction caused by the disease.

In reconstructing a nose a surgeon must be sure that three things are provided and if one or more are absent they must be supplied. There must be skin to cover all raw surfaces. This is obvious. There must be present a suitable framework to support the nose else the normal muscular action and the physiological tension of the tissues impair the result. The third necessity and the last to be recognized is that of providing an epithelial lining. When this is not done the exposed connective tissue contracts overcoming the correction. The lining may be mucous membrane, full thickness skin from adjacent or distant regions or perhaps Thiersch grafts.

When transferring skin from a distant part the tubular graft of Gillies may be used advantageously. The flap may be taken from the chest, forehead or top of head. Having outlined the flap required extend the incision in such a manner that there is a long pedicle properly placed. Then fold the pedicle on itself laterally, and unite the edges with sutures. Usually the pedicle is cut and tubulated and some days later when the blood supply has become established the flap is separated and placed in position. When the flap has united to its new bed the pedicle is severed, opened and returned to its original location, and the flap adjusted as may be indicated. When cutting the flap do not allow too much for contraction. Pickerell has described a method of transferring skin in which the tube is used as the graft.

The loss of substance of the nose and the portion deficient varies. Any type may be met with. There may be loss of the upper, middle of lower portion or combinations of these beginning either above or below. In addition to these the depth of the injury varies as regards loss of tissue. It is not necessary to consider each of the possible injuries and the combinations and distortions that may occur. There are a great many procedures to choose from when reconstructing a nose as almost a hundred different methods of obtaining the skin flap alone are described by various writers. The surgeon must call upon his knowledge, experience and ingenuity in meeting the conditions present.

The bridge of the nose may be flattened without destruction of tissue, there may be destruction of cartilage or cartilage and bone may both be destroyed in addition to the soft structures. The condition may be congenital or the result of disease or trauma. The depression may be high or low.

The easiest method of correcting a saddle nose is by the injection of some paraffine mixture. The immediate results of this treatment are all that could be expected but the aftereffects are sometimes not so good and I would advise against using this simple method, or, in fact, against putting any paraffine containing mixtures into the tissues anywhere. When injected these mixtures are taken care of in the body in one of two ways. They may become encapsulated and lie dormant or they may stimulate the growth of connective tissue and produce disfiguring growths. They are never absorbed.

Paraffine in the tissues is fine so long as it lies dormant but one can never tell how long this will be and which patients are the ones in whom paraffinomas will occur. When the injected material starts to enlarge it should be removed to overcome the disfigurement. Those who have been called upon to remove paraffine realize the great difficulties involved in so doing, as it is almost like trying to remove wax from a sponge.

The method which is applicable to most saddle noses and which gives the best results is that of building up the defect with rib cartilage, celluloid or ivory. I have found that when cartilage is used the patient suffers more inconvenience, by far, from the operation necessary to obtain the cartilage than they do from the work done on the nose. While cartilage is always at hand, is easily shaped and retains its size and shape, the same applies to celluloid to even a greater extent with the added advantage that there is only one incision and the patient is saved considerable pain.

The celluloid is properly shaped in the office and is perforated with a number of small holes to aid in its being held in position. I have never found celluloid to cause the least bit of trouble after being put into position. It seems not to cause any reaction in the tissues and is not absorbed.

(To be concluded)

The Diagnosis of Engagement in Vertex Presentations

MEYER ROSENSOHN, M.D.

New York

The importance of engagement in vertex presentations cannot be over emphasized when it is realized that, in the vast majority of cases, the engaged head will come through the natural passages. Nonengagement, with active labor, indicates some abnormality, and where such a condition exists the case may come to interference by Cæsarean section. Even in the funnel or male type of pelvis with its contracted outlet the delivery can usually be accomplished *per vias naturales*.

Realizing, then, the significance of engagement, it becomes of the utmost importance to recognize its presence or absence in the given case. To facilitate its diagnosis this brief paper has been written, the comprehension of which depends upon the following well known facts.

The biparietal diameter and circumference represent the widest breadth and perimeter of the fetal skull; above and below this, the head becomes smaller. If the head of a newborn baby is felt with the hands, beginning at the vertex and palpating downwards to the neck, it will be seen that the hands at first diverge until the parietal bosses are reached; here they are farthest apart. As the neck is approached they slowly approximate.

Fig. 1.—Nonengaged vertex.

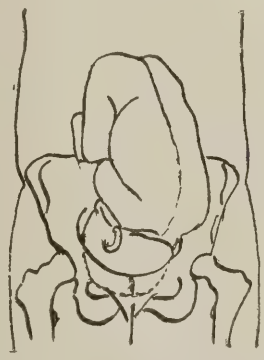

Fig. 2.—Engaged vertex.

(From Williams's *Obstetrics*)

Applying this to the abdominal examination of the fetus in utero, it must be kept in mind that the part of the skull below the brim cannot be felt. With both hands on the lower abdomen, there is, ordinarily, no difficulty in vertex presentations, in feeling the head. As one palpates from the body downward, the hands diverge on the skull. If the pelvis is encountered at this point, and no more of the head is felt, it is because the biparietal circumference is below and the vertex engaged. But if the hands, after diverging on the fetal skull, are found to be approximating, i. e., drawing near to the median line, it is then apparent that the biparietal diameter and circumference are above the brim, and the head, therefore, not engaged.

If the same idea is kept in mind in making the vaginal examination, the fingers on the vertex move outward; if there is no engagement, the fingers continue to move outward and the brim is felt below. Whether the head be small or large, or the uterus tonic or relaxed, by such vaginal palpation one can easily determine if the portion of the head above the brim is wider or narrower than the part below. Nonengagement is indicated if the fingers go outward towards the sides of the pelvis; engagement, if the fingers move towards the median line.

There is no great difficulty in applying this simple theoretical procedure even in the tall male type of pelvis, for here, in case of doubt, an examination under anesthesia will readily reveal the condition. The diagrams appended illustrate the application of the principle referred to above.

SUMMARY

1. In vertex presentations engagement can be readily determined.

2. In an abdominal examination the vertex is engaged if the hands diverge in palpating the head; the head is nonengaged if the hands converge.

3. In a vaginal examination the vertex is not engaged if the fingers continue to move outwards relative to the brim.

20 West Fiftieth Street.

Parenteral Ferments at the Service of Immunity from the Viewpoint of Evolution

FERDINAND HERB, M.D.
Chicago

Beginning with the observation by Metchnikoff of the phenomenon of phagocytosis, the defensive mechanism of the human body gradually disclosed itself more and more as based upon a process of digestion. But while this basic conception is generally acknowledged as correct, many of the details of the process have remained in utter darkness, in spite of the tremendous and zealous work expended to grasp their meaning. Much of this condition of affairs is due, I believe, to our regretful lack of information as to the agents that perform digestion, namely, the ferments. It is, indeed, difficult, if not impossible, to form a correct opinion of, and to view intelligently, many of those phenomena of infection and immunity that still baffle us today unless the nature of the ferments, their origin and distribution, and their behavior under the ever changing conditions of health and disease become known more minutely. More light on the subject of ferments, and particularly of parenteral ferments, will, therefore, undoubtedly prove of great assistance in our quest to pierce the mysteries shrouding many of the phenomena of immunity. With the actors, that is, the ferments, better understood, the entire performance must, of necessity, gain decidedly in transparency and lucidity.

A general characterization of the ferments, so far as their differentiation and mode of action are concerned, has been given in a comparison of enteral and parenteral ferments furnished at an earlier date (1). It is our object now to show the latter, the parenteral ferments, from a general viewpoint at the service of immunity—staged as actors in the drama of infection, as they progress from their simple beginnings in the lowest forms of life to their elaborate working system, which exists today in the highest animals and in man.

The different parenteral ferments, that is, the ferments of the blood and tissues outside of the alimentary canal, have been given various names and are known as agglutinins, precipitins, lysins, amboceptors, antibodies, antitoxins, and so on. The inclusion of the antitoxins among the ferments may not correspond with the generally accepted view, but is fully justified from a scientific biological viewpoint, as I have shown in various papers (2, 3, 4). If, therefore, in the following lines the familiar word antitoxin is used for the purpose of facilitating the understanding, it should not confuse the fact that antitoxins are ordinary digestive ferments, obeying the same identical laws as other parenteral ferments do.

In our effort to disentangle the confusing mass of observations made in regard to ferments and their influence upon infection and immunity, and to establish a scientific basis for further studies, it will prove of great advantage to approach our problem from an evolutionary viewpoint by following the parenteral ferments during the ascendency of living creatures from their humblest beginnings to their highest stages of development. It is only in this way that many of the most perplexing and seemingly inscrutable immunity phenomena find a ready and plausible explanation.

The unicellular organisms that sprang into existence at the very dawn of budding life engulfed their food and prepared it for assimilation within their protoplasm. Each cell, therefore, digested its own food independent of other cells, just as in the dim, prehistoric ages each caveman fought his own battles. The most characteristic feature of this intracellular digestion, so far as it concerns us here, is the fact that the elaborated digestive ferments were retained strictly within the cell and did not appear in the surrounding fluid, just as it is the case, for instance, in the ameba of the present day.

As cells began to group together in the course of evolution to form more complicated beings, intracellular digestion was, at first, continued. As before, the food was engulfed by the individual cells and digested within their protoplasm, Metchnikoff found this intracellular digestion in existence still today in many animals of the lowest order, for instance, in actinians and molluscs, in spite of the fact that these creatures already have a special digestive organ. No ferments, however, are extruded into this alimentary canal. The food taken up enters the cells lining this canal and is there digested.

With the progress of evolution in the course of millions of years intracellular digestion was gradually abandoned. A community spirit, and with it a division of labor, developed, as one individual cell became more or less dependent upon the other. Consequently, concerted action became the order. This was true especially with reference to digestion. Its intracellular form gradually changed into the extracellular variety. Cells no longer performed this function individually. They ceased to depend entirely upon their own resources, just as human beings later on began to form communities, tribes and nations for mutual protection and united action. Ferments began to leave the cells to serve a common good. Consequently, in enteral digestion, digestive fluids with their ferments poured into the stomach and the bowels; while in parenteral digestion digestive ferments gathered in the serum.

This extracellular digestion, characterized by the extrusion of ferments from the cells into the surrounding fluids, is now preponderant in all higher living beings. However, even in the highest animals and in man, intracellular digestion is not entirely given up. It still exists side by side with extracellular digestion. There are even instances known where digestion may be placed at will within or without the cells. Metchnikoff gave us a striking example of this kind. If an alligator, kept at about 20° C., is injected with tetanus toxins, the poisons rapidly vanish from the blood without the appearance of

antitoxins in the serum. However, if an alligator is kept at a temperature of from 32° to 37° C., the injected toxins vanish while antitoxins appear in the blood in great numbers. In the first instance, while living conditions approach those of animals of the lower order, the toxins are destroyed within the cells by intracellular digestion and no specific ferments are extruded into the serum; in the second instance, while living conditions approach those of animals of the higher order, the extracellular digestion of the injected toxins is employed with an outpouring of ferments from the cells into the surrounding fluids.

But also in warmblooded animals, the cells which ordinarily extrude the ferments can be forced to return again to the aboriginal, intracellular digestion with its retention of ferments within the protoplasm if unusually heavy or long continued labor is imposed upon them and extraordinary efforts must be made to cope with the situation. Intracellular digestion is not only the aboriginal but also the more powerful and, therefore, the more efficacious digestion.

Conditions of this kind, effecting a reversal from the extracellular to the intracellular digestion, are caused artificially when, in order to produce antisera, specific toxins are injected into animals regularly for a long time. Thus, producers of antisera have found to their utter surprise and great dismay that horses, which are used, for instance, for the production of antidiphtheritic serum, after an initial abundant production of antibodies sooner or later arrive at a point where the specific antitoxins, in spite of continued injections of toxins, grow less and less in numbers, while the immunity continues to rise to its highest peak. "Paradox" cases of this kind have been reported by Behring, Roux and other observers without, however, giving any explanation as to the cause of this puzzling phenomenon. The assumption, as advanced by Sahli (5) and others, that the steady decrease in antitoxins is due to the exhaustion of the cells, can hardly be accepted. Progressive exhaustion of the cells would lead to a decreased and not, possibly, to an increased ability to work, as it is shown to exist by the continued rise of immunity. It is only from the viewpoint of evolution that a plausible explanation is possible. Under the load of work imposed upon them in consequence of the long continued injections of toxins, the cells of the horse, to meet the emergency, return gradually from extracellular to intracellular digestion, so that in spite of the continually rising degree of immunity less and less ferments appear in the blood.

There are also, even in the human body, places where intracellular digestion is retained permanently by Nature for the special purpose to suppress infections at their very beginning with the most effective means at her disposal. Intracellular digestion is, therefore, retained at such places of the body that are exposed peculiarly to certain infections and serve as portals of entry to their respective germs. Hence, we find this kind of digestion in the lungs, the throat and the urethra. As proof may be cited the well known clinical facts that occasionally in favorable cases of pneumonia, in light cases of diphtheria and in uncomplicated cases of gonorrhea antitoxins do not appear in the blood.

This circumscribed, local intracellular digestion at exposed places of the body is a very practical and extremely effective measure employed by Nature. The protection, thus granted, shall hereafter for convenience sake be designated as "portal protection"; and the local immunity developed at such places be called "portal immunity."

In the general scheme employed by the body when fighting infections the portal protection forms the first line of defense. The nonappearance of specific ferments, or antitoxins, in the blood during or after a given case of bacterial invasion is, therefore, proof that this first line of defense was not broken. Not until the portal cells succumb and the white cells of the blood, which form the second line of defense, begin to participate in the battle in large numbers, do specific ferments aggregate in the serum, as now the intracellular digestion of the portal cells is gradually supplanted by the extracellular digestion of the leucocytes. However, the enormous number of antibodies we frequently find in the blood during the course of infectious diseases does not make its appearance until also the third line of defense, namely, the fixed cells of Aschhoff's reticuloendothelial digestive apparatus, becomes engaged in the struggle. This third line of defense is by far the most extensive and, therefore, the most powerful. It gets, however, not active until the invading organisms appear in the blood and lymph, and thus, can be taken up directly by these fixed cells themselves.

Further clinical examples of localized intracellular digestion at portals of entry are not wanting. They represent some of the most puzzling phenomena that have been brought to light during immunological researches. But, though their more minute presentation is reserved for a later paper dealing with the biology of positive and negative skin reactions, one may be given here to typify this class by referring to the experiments of Frankenstein (6). In twenty infants from three to ten months old, he was unable to demonstrate four to twelve months after smallpox vaccination in any instance the antibodies in the blood that are always demonstrable in adults under such circumstances. Nevertheless, there occurred in all children that were revaccinated four weeks later an earlier reaction, proving that with the first vaccination a partial immunity had been accomplished, that is to say, that specific ferments had, indeed, been developed but were retained within the cells—an evolutionary quality of the skin of infants that is lost in later days. The modus operandi of the portal protection, characterized by intracellular digestion with the absence of ferments from the blood stream, gives us also here a ready and plausible explanation.

In all instances described above the ferments appearing in the blood are derived from living, functioning cells. Bergel (7) was able to follow the process of their extrusion under the microscope by observing the gradual development of agglutination and lysis of erythrocytes around macrophages that were busy digesting devoured red cells.

The extrusion of ferments is, therefore, physiological under such circumstances. It follows definite laws and can be studied in all its details when specific particulate antigens, such as the blood of pigeons or sperma, are inoculated into the abdominal

cavity of nonimmune animals. Such experiments were first conducted by A. Wolff (8). Without exception, the reaction began with phagocytosis and intracellular digestion. But even phagocytosis was very slow at first, so long as the cells of the experimental animal were still untrained. Thus, after the first injection, it took twelve to fifteen hours until a few of the injected blood or sperma cells could be detected within the phagocytes, while not until after sixty-four hours a few scattered instances of extracellular lysis by extruded ferments made their appearance. After the second injection, phagocytosis progressed at a lively rate already after one and one half hours and was accompanied by a widespread extracellular lysis. After the third injection, extracellular lysis was already completed before phagocytes appeared on the field of action.

So we see that the first stages in the development of immunity still today are ushered in by the same aboriginal phagocytosis with intracellular digestion with which the first living beings started out on the road to ascendency. Here, as well as there, the higher stages of development, characterized by the extrusion of ferments and extracellular digestion, follow later. These experiments of Wolff, thus present the entire process of evolution in a nutshell, so to speak, with the only difference that Nature accomplishes now within comparatively few hours what took millions of years of experimentation for its development. They furnish but one of those numerous instances which allow the initiated to retrace Nature's steps and to dissect the different stages in the evolution of immunity with the same precision as we can dissect the progressive stages in the evolution of the human embryo by following its growth in its mother's womb.

The initial slowness of the elaboration and extrusion of specific ferments, as amplified above, is of greatest clinical importance, inasmuch as in the case of infectious diseases the invading specific organisms have ample time for extensive multiplication and distribution throughout the body before the defensive mechanism of the host has developed sufficiently to encroach upon their progress. The efficacy of antisera, for instance, of antidiphtheritic serum, is, under these circumstances, due to the fact that their specific ferments, incorrectly called antitoxins, supply, when injected with the serum, the urgently needed defensive ferments at a time when the body is still unable to furnish them, so that the battle against the invaders can begin effectively at a much earlier time.

This highly developed mechanism of parenteral digestion with its extrusion of ferments into the blood and extracellular digestion is not employed by the body unless the foreign antigen, presented in the body substance of the invading organisms, consists of protein, as is ordinarily the case. However, if the foreign antigen consists of fat or fatlike substances, the conditions are reversed. Fat and fatlike substances, for instance, the body substance of the tubercle bacillus or of the treponema, can be digested only intracellularly. The parenteral digestion of fat is, even in the highly developed body of man, to a great extent still in its original, primordial condition. This fact stands out also in enteral digestion. In the bowels, too, the digestion of fat by fat splitting ferments has, up to the present day, remained upon a low state of development and is in its efficacy millions of years behind the digestion of protein.

A number of experimental findings confirm the intracellular digestion of fat and fatlike substances: 1. According to Doerr (9), "it has not been proved that the injection of tuberculin into normal human beings or animals leads to the elaboration of precipitins and agglutinins." 2. Parenteral injection of pure fats or lipoids does not increase the lipolytic action of the blood or only slightly. Lipolytic ferments are, consequently, not extruded into the blood during the digestion of the injected material—a characteristic of intracellular digestion. It is due to this fact that therapeutic sera, which depend for their efficacy upon the presence of specific ferments, have so far not been developed against tuberculosis and syphilis and have no prospect to be developed hereafter. 3. Lipoids, when pure, do not cause anaphylaxis, as this phenomenon predisposes the presence of specific ferments in the blood (10).

Fat and fatlike substances not only require for their disposal intracellular digestion but also the intervention of special cells, namely, of those cells that are able to elaborate fat splitting ferments. To these cells belong principally the lymphocytes and their derivatives, the plasma cells (11). It is for this reason that these two kinds of cells predominate in the cellular infiltrations encountered in tuberculosis and syphilis. Of the fixed cells, the endothelial cells of the blood and the lymph vessels, too, elaborate lipolytic ferments in addition to their proteolytic ferments. They play, therefore, an important part in the battle of the body against these two infections. The polymorphonuclear leucocytes have only proteolytic ferments and, consequently, cannot participate in the struggle against tuberculosis and syphilis (12).

Nevertheless, there are circumstances under which specific ferments appear in the blood during the course of tuberculosis and syphilis. But their appearance is, then, not physiological, as they are not extruded by living, functioning cells. It is pathological. They are thrown into the circulation in consequence of the death and dissolution of the cell. The interesting details of this extremely important immunological phenomenon are not germane to our present topic and are reserved for a later paper at their proper place.

Endemic Influenza

C. G. FIELD, M.D.
Sierra Madre, California

The general practitioner, who sees diseases at their beginnings, has, during the past few years, yielded to the usual demand for an immediate diagnosis and now has a tendency to call almost all acute conditions influenza. Due to the fact that most acute conditions, and the initial stage of many chronic disorders (more perhaps than we now suspect) begin with fever and signs of upper respiratory inflammation, the term influenza will fit nearly all of them at this stage. When the fully developed disease appears it is conveniently called a sequel. In this way contagious diseases, during the early stages when most easily disseminated, are usually called influenza. This tendency for physicians, as well as laymen, to call almost any acute condition influenza, not only aids in the spread of contagious diseases, but often leads to disastrous results for the patient. More pernicious is its tendency to obscure our researches into the beginnings of disease. For these reasons, as well as several others which I will mention later, it would seem advisable to replace this term with one not bearing such a degree of finality.

Death not infrequently results in cases where the patient might have been saved by surgery or some other specific mode of therapy, had not the facile diagnosis of influenza lulled those concerned into a false state of security. Children with fever and abdominal pain are often said to have "abdominal flu" and prove later to be suffering from appendicitis or intussusception. In such cases how much better it would be if we would remain on our guard, using such terms as "fever of unknown origin," or "febricula," or, if further mysticism is necessary to save one's pride, "ephemeral fever." Such terms will at least fool only the lay people, and not the physician as does "influenza" so frequently now.

The fact that patients get well after running a fever for a few days without the development of other symptoms, is apt to be taken as proof that the condition was really influenza. This is not necessarily the case, because so many of our infectious diseases present abortive forms. In only a small proportion of poliomyelitis cases, for instance, does paralysis ever develop. The nonparalytic cases are invariably called influenza. It is undoubtedly these cases which are responsible for the spread of poliomyelitis. A short time ago I saw a boy who had become paralyzed in both legs. One week previously he and his seven brothers and sisters all had an attack of fever which was called "summer flu." Undoubtedly they all had poliomyelitis, but fortunately paralysis developed in only one. There had, of course, been no institution of quarantine and several more cases developed in the neighborhood with the usual number of cripples resulting.

During the great pandemic of 1918 it was comparatively safe to call any case with fever and signs of upper respiratory infection influenza. Even at that time an occasional case turned out to be pyelitis, mastoiditis, or something else before the end. These latter conditions were then usually considered complications or sequelæ, which was certainly not always the case. The original fever was more likely the prodromal signs of the disease which became obvious later when well known peculiarities developed. During epidemics, unfortunately, due to our present lack of knowledge concerning this disease, such mistakes seem unavoidable. In the case of endemic influenza, however, such mistakes can be avoided by the simple expedient of using a less irrevocable term. The present plan of calling the prodromes 'influenza' and the fully developed disease a sequel, has resulted in the absurd belief that practically all the afflictions to which human flesh is heir are sequelæ of influenza.

Often tuberculosis patients state that they had several attacks of influenza which finally resulted in tuberculosis. Their sanatorium histories refer to these attacks of influenza without questioning the diagnoses. The old lunger tells you that his tuberculosis no longer bothers him, but that he has frequent attacks of "flu" (which do not require the rest, etc., which he knows would be necessary if he were having tuberculosis flareups.) All too frequently his physician fails to perceive the error in his reasoning.

Sir James McKenzie emphasized the importance of closer study of the beginnings of disease. This stage is seen only by the patient and the general practitioner, both of whom are so prone to call everything influenza. The general practitioner, in his important rôle as observer of the beginnings of disease, instead of helping to clarify matters, as did Sydenham, is casting a veritable veil over our clinical researches by his constant use of the meaningless term, "influenza." For instance, it is believed that epidemic encephalitis may be a sequel of influenza largely because so many of the patients give a history of recently having had influenza. Is this socalled influenza not more likely the onset fever of encephalitis? There is little more reason to call this initial fever influenza than to call the onset fever of poliomyelitis influenza. Homer Swift (1) has recently pointed out that rheumatic fever, and many other diseases no doubt, show different types of manifestations at different stages (like syphilis) and at present we recognize only the later stages. How are we ever to recognize these early stages if they continue to masquerade under the guise of influenza as they are undoubtedly doing at present?

For a number of years, in taking the past medical history, it has been customary to question a diagnosis of typhoid fever because it was realized that the beginnings of such diseases as tuberculosis, syphiliis, etc., were often erroneously called typhoid. For the same reason it is now high time we look askance on a diagnosis of influenza.

Fever is the general reaction of the body to an

infection and is the background of the symptomatology of infectious diseases. Separation into entities depends upon peculiarities other than the fever syndrome. Influenza, having no such peculiarity, is, apparently, the residue of acute fevers left after removing those accompanied by some pathognomonic feature. In this respect it bears much the same relation to acute diseases as neurasthenia bears to chronic diseases; and, as in the case of the latter, the number of influenza diagnoses bears an inverse ratio to the amount of study given to cases.

Upon closer observation the "nervous influenza" case will frequently prove to be encephalitis, apical pneumonia, chorea or one of the meningitides; the "respiratory influenza" case, measles, poliomyelitis, or tuberculosis; the "abdominal influenza" case, appendicitis, intussusception, food poisoning or dysentery; the "febrile influenza" case, pyelitis, mastoiditis, rheumatic fever or bacterial endocarditis; and the "summer flu" case, poliomyelitis or typhoid. An "influenza" case is, therefore, one calling for the utmost care in study and observation. Rather than easy, as is commonly supposed, it is very difficult to diagnose. Rather than common, it is probably rare and it seems entirely possible that further study might eliminate it altogether. There are no definite criteria by which to diagnose it; its etiology is unknown; there is no definite pathological picture; its course is uncertain; and its symptomatology is devoid of any peculiarity. Since relinquishing the Pfeiffer bacillus as the probable cause, the existence of endemic influenza as a separate entity rests chiefly on the theory, that since we are unable to trace the origin of the pandemics, certain of our "colds" may be mild forms of the disease which serve to carry along the infection until some unknown factor raises its virulence. This certainly seems logical, but, in the absence of differential criteria, are we warranted in attempting to state just which of these colds are responsible for this sinister influence?

The superficial manner in which physicians arrive at a diagnosis of influenza has naturally led lay people to the conclusion that it is very easy to diagnose. They have therefore ceased calling him for fevers, feeling (quite correctly in most cases) that he will say "flu" and give aspirin, both of which they are quite able to do themselves.

As the title indicates, our criticism of the term "influenza" refers only to the endemic type and has no reference to the great pandemics. The same criticisms, however, no doubt apply to the numerous lesser epidemics which have been reported each winter since 1918.

CONCLUSIONS

The term "endemic influenza" should seldom, if ever, be used because:

1. It is casting a veil over our search for the beginnings of disease.
2. It aids in the spread of infectious diseases.
3. It delays diagnosis and specific treatment.
4. It encourages lay people to disregard acute fevers.
5. "Fever of unknown origin," and "febricula" are not subject to these objections.

The Diagnosis and Conservative Treatment of Renal Calculi

A. STRACHSTEIN, M.D.
New York

The origin of renal calculi is as yet not clearly understood, although it is accepted by many that there are certain contributing factors. These are stasis and interference of the urinary flow, as well as infection. The urine is more than a mere watery solution of certain salts, for, as Walker states, it has the power of holding a greater proportion of some salts in solution than has distilled water.

Spitzer and Hilkowitz maintain that the urine contains normally a number of colloids delicately balanced to maintain the solubility of solids. When this is thrown out of equilibrium by any pathological process, be it of metabolism or alteration in the urinary passages, the formation of calculi is favored. Thus there is no necessity for a stone nucleus, as any colloid thrown out of suspension may be the starting point for stone formation. On the other hand I have met with cases of long standing persistent phosphaturia, where the urine never failed to show many visible particles of what proved microscopically to be earthy phosphates, and yet no calculi formed in the kidneys or bladder, after having been observed for six years. I shall, however, not delve any further into the etiology, since we are now more concerned with the diagnosis and treatment.

Modern urology calls for the intelligent interpretation and use of the cystoscope, x ray, pyelogram, x ray catheters as well as renal function determinaiton. These agencies make it pleasurable to pursue the practice of our specialty and one often wonders how our confrères of years ago could possibly do without them. Nevertheless there are cases where the x ray is of little or no help and one must be on his guard before coming to any definite conclusion. From the clinical point of view patients with renal calculi divide themselves arbitrarily into the following groups:

I. This group includes cases presenting classical symptoms of pain in the posterior renal area which may or may not radiate to the groin, along with other well known symptoms. Then ureter catheterization will often meet with obstruction on the side in question, depending on the size and position of the calculus. The ureter catheter may on a second examination still find the obstruction or will sometimes pass beyond the calculus. When the x ray reveals a shadow at the corresponding point, it makes the diag-

nosis of ureter calculus conclusive. One must, however, be on his guard and assure himself by the use of the x ray catheters that the given shadow is in the ureter and not a phlebolith. Bransford Lewis has an ingenious method which may be used with certain modifications in questionable shadows.

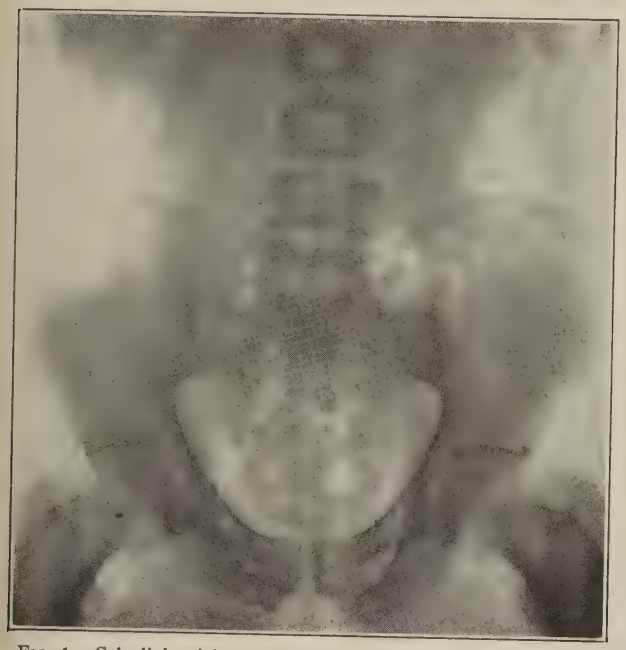

FIG. 1.—Calculi in right ureter, dislodged after four manipulations.

As pointed out by Guy L. Hunner, the incidence of stricture associated with stone is frequently found in the ureter and must not be overlooked.

II. There are cases where all symptoms point to an acute abdominal condition and if the affection is in the right lower quadrant, it creates a misleading picture. Thus, if the calculus is lodged in the lowermost part of the right ureter, the symptoms will often simulate acute appendicitis. Cystoscopic examination will often show edema of the right ureter opening and also obstruction to a passing ureter catheter. Such cases become especially perplexing when the x ray does not reveal any shadow of a calculus. One such case, that of a young woman, came under my observation recently. The patient's relatives were told that although the x ray did not reveal any shadow of a stone, the diagnosis was nevertheless made of ureteral calculus. Not contented, the patient left the hospital and was placed under the care of a well known surgeon who promptly performed an appendectomy. Four days later there developed a violent attack of right renal colic which necessitated another operation during which a calculus was removed from the lower third of the right ureter.

III. Perhaps the most fascinating cases for diagnosis are, a, those presenting clinical symptoms of stone on one side, and revealing a stone by x ray and ureter catheterization on the opposite side; also b, those cases presenting clinical symptoms of stone on one side, although the stone is on the opposite side, without showing any x ray shadow at all. A patient may be brought to the hospital with symptoms simulating appendicitis. Ureter catheterization may or may not reveal an obstruction, but the x ray will show a shadow on the opposite side (Fig. 2). Then again, the same renorenal reflex may be present without the x ray revealing a shadow, but if the stone is in the lowermost end of the ureter, edema will be present at the ureter orifice, as well as partial or complete obstruction to the passage of a ureter catheter. In two of my recent cases the attacks of pain were constantly on the opposite side of where the calculi were lodged, but often ureter catheterization and pyelography, the spasmodic renal colic attacks shifted towards the truly affected side and never again involved the opposite side.

IV. Calculi in the kidney or renal pelvis proper show a wide range of variety. There are quiescent stones that may be lodged for many years causing various degrees of destruction to the renal parenchyma and yet cause no other symptoms beyond those of an occasional dull backache, or those of chronic cystitis.

Some twelve years ago I called with a patient on Professor Israel for consultation. The patient showed several calculi in both kidneys. He advised without further delay to operate on the worst side, for the removal of the calculi. The patient being a busy man and wavering, neglected to do so and still carries the stones with him to this day, although the bladder symptoms are increased and the renal function on the worst side is markedly impaired. But not all patients will escape with so little hazard by disregarding the necessity of dislodgement of one or more calculi in the pelvis when infection takes place. Their presence as is known, sets up a pyelitis leading to calculous pyonephrosis and ultimately producing sacculated local abscesses with complete destruction of the parenchyma (Fig. 3). The lesion does not stop here, but will eventually cause cystitis with an ascending infection of the opposite side.

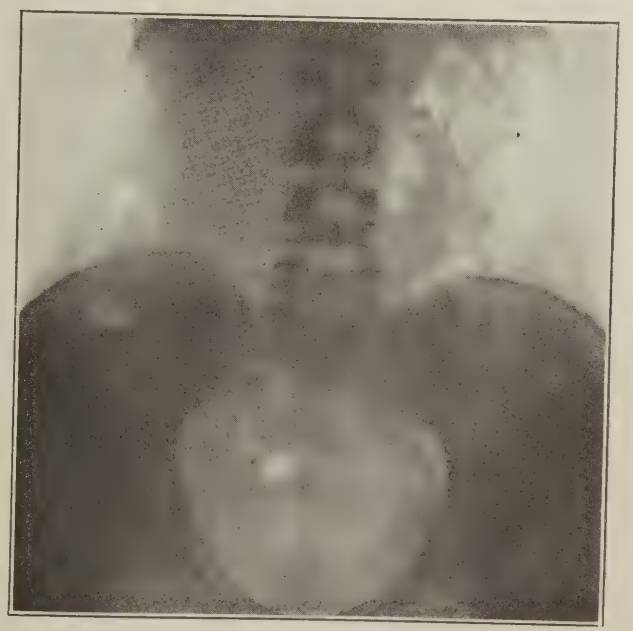

FIG. 2.—Calculus in the left renal pelvis (case III) giving rise to symptoms simulating appendicitis.

It is our aim to plead for the use of conservative methods for the removal of ureteral calculi, especially in unimpacted cases. The nonsurgical removal has

been used by many urologists before. My own experience only confirms previous findings of others, strongly endorsing such manipulations. The basic principle of the treatment lies in dilatation of the ureters plus lubrication. To accomplish this, the maximum amount of anesthesia is desired of the bladder,

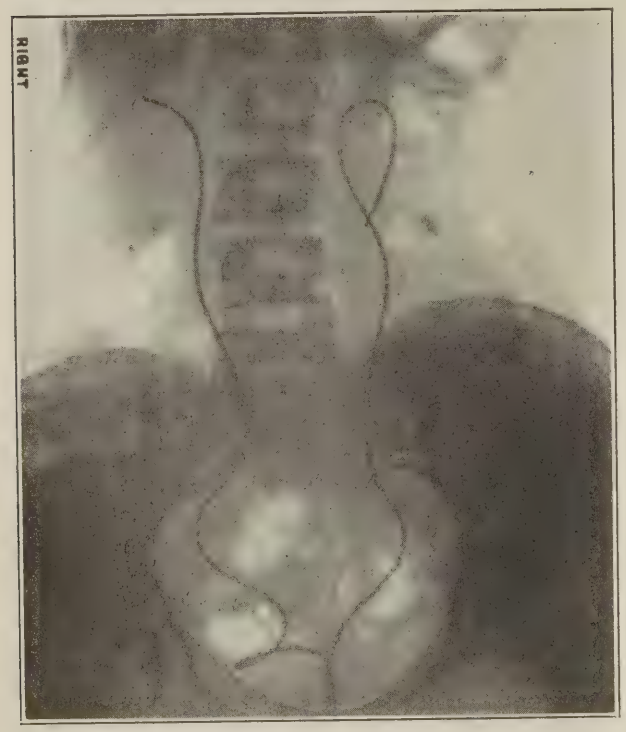

Fig. 3.—Same case as Fig. 2, with the ureteral catheter coiled up in the renal pelvis giving impression as if the shadow is extra renal.

urethra and ureters. We are in the habit of using the following routine:

About fifteen minutes prior to cystoscopy, a rectal suppository is inserted, containing half grain each of powdered opium and extract of belladonna. Then the urethra is distended with a two per cent. solution of novocaine which is held in by a penis clamp for at least ten minutes so that some of it invariably oozes back into the posterior urethra and bladder. Patients who had dreadful remembrances of previous painful cystoscopies often express surprise that the same examination can be performed with little or no pain or discomfort when this routine is carried out

I am in accord with Crowell when he states that most ureter stones may thus be removed by one of several manipulations.

After a given stone is located by the use of the cystoscope, we use on one side a No. 6. catheter and on the other side of the cystoscope a No. 6 or 7 stiff bougie. First the catheter is inserted and pushed up to the calculus, at which point the local anesthetic is injected, and wait for several minutes. Then we inject sterile olive oil and try now to move the catheter beyond the stone. Whether we succeed or not, we now use the bougie from the opposite side of the cystoscope without removing the catheter, but rather go along the side of same, thus getting the catheter and bougie at one sitting into the one ureter without inserting the cystoscope twice. This assures drainage as well as dilatation.

In office practice the bougie and catheter may be left *in situ* for one to two hours, whereas in the hospital it may be left in for twenty-four hours. While such one manipulation will sometimes cause expulsion of a stone several days later, other cases may require several manipulations with ultimate success. Of course if the stone is of large proportion and impacted in the lower end of the ureter for several months, there may be a considerable amount of ureteritis binding the stone down firmly. If no progress is noticeable or if no passage of a catheter or bougie is possible, one must resort to surgery. Crowell wisely states that "the simplicity and safety of this method is very evident." It is simple in that any one reasonably skilled in cystoscopy can do the work in his office or hospital with perfect safety without a general anesthetic or marked suffering on the part of the patient. It is safe because no trauma of consequence is produced—and in addition, the kidney's function not being inhibited, drainage frequently improves the renal function.

The treatment of calculi in the kidney or pelvis proper will depend very largely upon two factors, namely: a, the amount of pain and suffering caused; b, the presence of clear or infected urine and the extent of the renal function.

There being no appreciable pain or suffering, especially associated with aseptic urine, it may be wise to give the calculus a chance to descend if the size warrants same. If, however, there is considerable suffering experienced and associated with infection

Fig. 4.—Case III. Dilated pelvis, with the pyelographic fluid submerging the calculus lodged in the lower calyx.

and renal function impairment, then surgery is the method of choice.

Case I.—D. S., female, aged twenty-five, admitted to the Bronx Hospital (12906) with a history of having had two days previously a sudden severe attack of pain in the right lower quadrant of abdomen.

The pain did not radiate and subsided spontaneously. Two days later she experienced another sudden sharp severe attack of pain in the right upper quadrant of abdomen, near the costal margin and radiating to the back as well as to the groin. This pain was relieved by the hypodermic injection of morphine and the patient had several intermittent attacks after this one.

Cystoscopic examination revealed an obstruction to the ureter catheter on the right side about four inches above the bladder. The x ray revealed a shadow at the corresponding point. Four manipulations were done as described above, at intervals of one week. The pain stopped and the shadow as well as the obstruction disappeared as the stone passed.

Case II.—T. E., female, aged nineteen, admitted to Bronx Hospital January 20, 1925, with a history of having developed two days ago an attack of pain in the right lower quadrant of abdomen. The pains were stabbing in character and felt anteroposteriorly but not radiating in either direction. Patient vomited several times and had chilly sensation. She had a similar attack three weeks ago, but now the pain appeared most severe on urination, leaving a sense of rawness. An examination of the urine showed large traces of blood.

Cystoscopic examination revealed a normal bladder; ureter catheter goes up to the very pelvis of the left kidney. On right side, catheter met obstruction about two inches above the ureter orifice. X ray revealed normal outline of both kidneys, and no shadows of calculi.

A diagnosis of renal calculus was made irrespective of the negative x ray findings and patient was advised to wait for further observation and treatment. After a second examination with similar findings she left the hospital. She was operated upon for appendicitis at another institution, but four days later there developed another violent attack of renal colic and another exploration revealed a calculus at the lower third of right ureter.

Case III.—I. L., female, aged twenty-five, admitted to the hospital (13484) with the following history: On the day previous to admission she was seized with an attack of severe pain over the right lumbar region as well as in the lower right quadrant. There was no true radiation of pain, as it was simultaneous in both regions. No urinary symptoms. Cystoscopic examination revealed a normal bladder. The x ray ureter catheter met with no obstruction on either side. The x ray, however, revealed a shadow of quite a large stone in the opposite or left renal area. The first impression was that the shadow was extrarenal, but a pyelogram and another plate showed that the suspected shadow is covered by the pyelographic injection fluid and also showed a dilated pelvis. This made the diagnosis of a large calculus in one of the calyces conclusive. There was no means of enlarging the calculus in a descending process and a pyelotomy was performed.

Case IV.—J. D., aged thirty-five, male, gave the following history: Had his first attack of renal colic on the right side six months ago lasting several hours. The pain ceased under treatment but had a similar attack two days later. The x ray taken then was negative. He was seized with a severe constant pain over the right lower quadrant, which became more intense at urination. Noticed some blood in urine.

Cystoscopic examination revealed the following: Normal bladder. Right ureter normal and permitted the x ray catheter to pass practically to the renal pelvis. Left ureter while it appeared normal showed an obstruction two and a half inches above the ureter orifice, after having tried with several different catheters and bougies. The x ray film did not reveal any shadows, nor did the ureterogram show any stricture.

Treatment was given at the office and patient went home few hours later. Two days later there again developed a severe attack of pain, and this time over the left lower quadrant and none on the right. This now corresponded with the physical findings. Cystoscopy now revealed a very edematous left ureter opening, and obstruction to the catheters and bougies about three quarters of an inch above the orifice. Treatment as described above was now given. Four days later he reported that all pains had ceased and that the stone had passed.

Case V.—Mrs. M. L., aged forty-eight. Previous history revealed that six months ago she suffered from carbuncles on the vulva as well as on one ear. Present history: Nine days previously there developed sharp pain over the right renal region, at times radiating to the groin. Also complained then of frequency of urination and noticed hematuria. Cystoscopic examination revealed a diffuse cystitis, but both ureter openings appeared normal, no ulcerations or edema. The x ray catheter met with distinct obstruction on the right side about three inches above the orifice. Left one passed all the way up. A ureterogram revealed a stricture and a markedly dilated ureter above the stricture in the middle third of ureter on the right side. No shadows of calculi were visible.

The ureter was gradually dilated with bougies and catheters at intervals of about ten days and irrigated with silver nitrate one to three thousand. After four dilatations, no visible obstruction could be detected any longer. A few weeks later she wrote that she was feeling fine and free from any symptoms (Fig. 4).

With the exception of the first case, these cases were selected because of their atypical character and interest. In the entire series the sodium salicylate renal function test showed marked impairment of renal function whenever ureteral obstruction was found.

The Control of the White Blood Cells

BURR FERGUSON, M.D.
Birmingham, Ala.

Since the publication of my paper on induced leucocytosis (1) last October, letters have been received which expressed doubt as to the extreme importance of the white cells in the phenomena of resistance to infection. Fortunately there is a case of epithelioma under my observation and direction, a history of which, with plates, is my answer to the criticism.

The patient is a man of fifty-three, who has led an active life, largely in the open. Intestinal stasis and pyorrhea for many years, amebic colitis from June, 1917, until December, 1919, evidently caused by the prolonged stasis, for there were one hundred and twenty-five men in the company at the time of its onset, among whom there were no other cases. For this colitis he was treated for several weeks. The malady was finally successfully treated by a series of hypodermic injections of emetine, accompanied by large doses of subgalate of bismuth.

In April, 1922, there was an impacted gallstone, under the medical care of Dr. Nightingale, Southampton, and afterwards of Sir Arbuthnot Lane in London. The stone got through the duct on the fifth day. The history was otherwise negative, including the Wassermann test.

The foregoing account would seem to indicate that the next lesion of interest would be a cancer, thus proving the truth of the teachings of Sir Arbuthnot Lane, that all malignant growths have the field prepared for their activity by prolonged stasis and intestinal poisons.

In June, 1925, two small reddish brown spots were noticed over the left malar bone. One of these in particular slowly grew larger. About the middle of August I made a diagnosis of epithelioma. A few days thereafter it was necessary to have a control for counts before and after the intravenous injection of mercurochrome. This patient was used primarily for these counts and also to note the effect of the expected increase in white cells on the lesions.

Dr. Siegenbeek van Heukelom, in the Children's Hospital, made a count of white cells which was 8,000 per cm., administered seven and a half c. c. of a one per cent. solution of mercurochrome, and sixteen hours thereafter made another count, which was 9,500. Both lesions in the opinion of Dr. van Heukelom and myself appeared much better, and the smaller one disappeared. In about ten days the other, however, appeared a bit more active.

On October 2nd the patient was taken to the Radiotherapeutic Institution for a consultation. Lammers, Molenaar and van de Linden, röntgenologists, agreed that it was an epithelioma and advised the immediate application of radium. This was done under the direction of Molenaar for sixteen hours (800 milligram hours). An areola surrounding the lesion soon appeared, which rapidly grew larger, until the fourth day, when there was pronounced elevation and intense itching. The observer was now convinced that while the radium rays had actually destroyed the malignant cells, it had also stimulated the production of white cells, for the demolition and removal of the tissue which had gone to make up the growth.

On October 16th Lammers and Molenaar agreed with me that there were still some active malignant cells. Another application of radium was made for two hours (200 milligram hours) at the end of which a very different appearance was shown, from that which had followed the longer application. Now there were shrivelled, whitened epithelial cells, over an area of about half the size of the scab shown in Fig. 1, and just behind this a much smaller area of whitened cells at the site of the lesion spoken of before, and which had not been seen since the administration of the mercurochrome.

Fifty hours after the application of the radium for two hours, the count of white cells was 8,900.

There followed during the succeeeding days the formation of the scab, with a large areola, shown in Fig. 1. On October 28th the site of the lesion was indurated, somewhat elevated, and showed little tendency toward the throwing off of the scab. Determining to hasten this process and to make a photographic record of its progress, the patient was taken to a photographer to show the condition on that day. This is shown in Fig. 1. Then to van Heukelom for four tenths neosalvarsan in eight c. c. of water. The count twenty-four hours thereafter was 11,000 cm. and there was a noticeable difference in the appearance of the lesion, its elevation being much lower and appreciably softer. Forty-two hours after the injection of the neosalvarsan a second photograph was taken (Fig. 2). The difference in the size of the lesion, as well as the change in the surrounding areola, is shown. Fig. 3 was made on the fifth day after the neosalvarsan and shows still further progress. The four photographs taken in seven days show clearly the work of demolition of the white cells.

To make deductions which seem inevitable to me it appears that prolonged and continuous stasis is a necessary precursor of cancer, as Sir Arbuthnot Lane has so fully told in his many papers on this subject; that a daily formed stool is an indication of stasis; that the waste which is emptied today, for example, should have been done yesterday; that a copious use of liquid paraffine is an insurance against cancer. I also believe that the increase in white cells that follows the use of arsenical preparations is a useful adjunct to radium in malignant disease.

In all the preceding reports of the beneficial effects of the control of the white cells I have attempted to tell only what I have seen or known to be true from the reports of confrères with whom I have been associated. Now, however, that objections to the idea have been raised, I think of a means of proving it. So I make the suggestion, as follows:

If any scientific fact is well established it is that quinine is a specific against malaria. I believe, however, that it is not a specific, that it derives its potency from the stimulation of the production of white cells. A simple test for the proof or disproof of this belief

would be to give to an adult infected with furunculosis one gram of the bihydrochloride of quinine deep in the gluteal muscle. I know that in a strong man there will be an increase in white cells of five to six thousand in twenty-four hours. I believe that after three or four such injections there will be no more boils in that person.

I have never seen this done but I feel sure of results, so the belief is recorded.

There is only one constant element in immunity, whether innate or acquired, and that is phagocytosis. The extension and importance of this factor can no longer be denied.

We may even attempt to increase phagocytosis in surgical operations, especially in those on the peritoneal cavity, by setting up there an artificial aseptic inflammation by means of various substances, innocuous in themselves, which attract a large number of leucocytes. In laboratory practice this method is in daily use for the purpose of increasing the resistance of an animal against the intraperitoneal injections of various microorganisms, and Durham has suggested the extension of the same method to human medicine. Certain surgeons have already made attempts in this direction (2).

In a series of carefully controlled determinations Dr. Seager Thomas and I found that the administration of the following drugs stimulated the production of white blood cells: neosalvarsan, mercury, quinine, autogenous and stock vaccines, diphtheria antitoxin, colloidal manganese, turpentine, and whiskey. Clinical observations in the treatment of many infections seem to indicate that the most useful agents are those which produce the greatest increase in the white blood cells and the maintenance of that increase for the longest period. The known effects of the administration of the foregoing drugs appear to show that the principal factor in the demolition of pathological tissue, the repair of wounds and resistance to infection, is due to the number and activity of the white blood cells. In the control of these cells I have seen surer results, and a smaller number of failures than in any other plan in the treatment of infections.

Dr. Edward S. Cowles of New York reports the case of a patient who had suffered over a period of ten years from colitis due to streptococcus infection of the lower colon, with persistent recurrent attacks of diarrhoea, with blood and mucus, and acute tenderness over her abdomen.

Repeated bacteriological examinations were made of the feces by a New York laboratory, with always a final remark of this nature: "Streptococcus viridans has pathological significance especially when found in large numbers as was found in this instance." On March 3, 1926, stools were submitted to this laboratory for a complete analysis and report in order to isolate the germs, to grow them, and to make a thorough determination of them. This examination of the stool was completed March 18th, with the following final remarks: "Streptococci are predominant in practically all the aerobic cultures. Streptococcus viridans is not a normal inhabitant of the intestines and its presence has usually pathological significance. There is a distinct indication of an inflammatory condition in the intestines and it is reasonable to believe that streptococcus is the causative agent. In the cultures from the washed mucus streptococcus fecalis and streptococcus viridans were practically the only organisms recovered."

Immediately thereafter one injection of sulpharsphenamin (0.05 gr.) was given the patient, and four days later on consultation with me, an injection of salicylate of mercury, gr. I. Then on March 26th another specimen was submitted to the laboratory, with the following report, March 29th, in the final remarks: "In comparison with the previous specimen, this specimen shows a distinct improvement so far as the streptococcus infection is concerned. The streptococci have practically disappeared from the stool and instead the B. coli show greater viability which is always a favorable sign." The tenderness over the patient's abdomen has disappeared, the stools are normal in appearance, with no inflammation by external examination or proctoscopic examination.

Trichophytosis of the Glabrous Skin as a Clinical Problem

MOSES SCHOLTZ, M.D.
Los Angeles, Calif.

(*Concluded from page* 382)

DIFFERENTIATION FROM OTHER DERMATOSES

Among dermatoses to be differentiated from trichophytosis can be mentioned pityriasis rosea, which may present a close resemblance with a patchy disseminated ringworm of the body. The tawny yellowish color, festooned shape of the lesions, absence of itching and of the epidermal collarette, bathing trunk type of distribution and selflimited course and also the lack of tendency to secondary eczematization, would speak strongly for pityriasis rosea.

Seborrheic dermatitis, particularly located in axillæ and groins, may give rise to some confusion. However, on analysis of the morphological details differentiation can usually be made without difficulty. In seborrhea one usually finds lesions on the scalp characteristically descending from the hairline on the face, neck, sternum, and interscapular regions; the lesions show greasy, heavy, yellowish scales and itching is usually mild or absent. Another condition that may give rise to confusion in diagnosis is the socalled infectious eczematoid dermatitis described by Engman. Here also a detailed morphological analysis in most cases is sufficient to effect the differentiation.

Infectious eczematoid dermatitis caused by the staphylococci or more likely by a mixed infection of staphylococci and streptococci, presents, as a rule, a picture of impetiginous eczema with a marked exudation and crusting. It commonly follows a superficial trauma or abrasion, rapidly spreads by extension and quickly involves large areas of the body without any tendency to selective distribution. The patches are ill defined and diffuse—morphological features quite different from trichophytosis. Lack of itching and response to mercury ammoniate and staphylococcus vaccines supply additional differential features.

COMPLICATIONS OF TRICHOPHYTOSIS

The most common complications of trichophytosis are pyogenic infection and eczematization. The frequency of pyogenic infection is readily understood if we remember how itchy the lesions of trichophytosis are and how often the trichophytic vesicles are scratched open by the patient. In fact, the stormy development and acute distress caused by the pyogenic infection is often the very first symptom that prompts the patient to seek medical relief. Unfortunately it is too often that the attending practitioner fails to recognize that trichophytosis is the underlying primary condition and that the pyogenic infection is simply superimposed as an incidental feature.

All that is necessary for a correct interpretation of these cases is a study of the morphological details. One will have no trouble in detecting the characteristic extremely itchy, discrete, ruptured vesicles with epidermal collarette and scaly marginated edges.

ECZEMA AS A COMPLICATION OF TRICHOPHYTOSIS

The second important complication of trichophytosis is eczema. The intimate relationship of trichophytosis and eczema will be better understood if we recall that eczema is not a definite clinical entity but merely the most general protean type of skin reaction which can be brought about by any mechanical, chemical or bacterial irritant. Whether eczema is a secondary development, as a result of scratching, or can be caused primarily by epidermophyton fungus itself, is hard to determine. I believe that eczema is a secondary development due to scratching, rubbing, and other incidental irritating factors, such as hot weather, perspiration, etc., since quite often we see clearcut cases of vesicular and scaly trichophytosis without any evidence of secondary eczematization.

A fact of clinical importance is that only in the very acute stage of eczematoid ringworm does eczema dominate the clinical picture so strongly that the underlying trichophytosis can remain unnoticed. As soon as the acute stage is over the clinical characteristics of trichophytosis, such as vesicles with epidermic collarette and marginated scaly edges, will be found, if looked for.

LICHENIFICATION

In my experience lichenification is a rather rare complication of trichophytosis. This furnishes another differential point from eczema since the latter shows a constant tendency toward lichenification. The type of trichophytosis showing the greatest tendency towards lichenification is tinea cruris.

TREATMENT

The treatment of trichophytosis presents a serious and rather puzzling problem. In the face of the parasitic nature of the disease and the superficial localization of the fungus it would seem that trichophytosis should yield to local applications of antiseptic ointments promptly and lastingly. Yet clinical experience shows that while the improvement of clinical symptoms is rapidly obtainable the clinical cure is hard to obtain in many cases, and certain types, such as palmar and plantar scaly trichophytoses, are exceedingly stubborn and resistant to all kinds of treatment and show a strong tendency to recurrence.

In my experience, the types of trichophytosis most easily controlled are the intertriginous and vesicular of the hands and feet; next come the axillary and inguinal types, the most resistant being the palmar, plantar, and keratotic types. Two explanations suggest themselves to account for the frequent recurrences after an apparent clinical cure. The first is that it is hard to dislodge all the fungi cells from the deeper layers of the skin. The second assumes that the recurrences take place from the spores that had escaped destruction from local applications, or from articles of clothing or bedding that have escaped sterilization. I believe that the second factor is responsible for a great many more recurrences than the first.

Speaking of the treatment as such, it seems that all

agree on the general plan, i. e., to eradicate the fungi by persistent cleansing with soap and water and antiseptic applications. But the number of antizymotic drugs is so large that here the general agreement ends, and everybody chooses a drug of his personal preference. The most commonly used drugs are: salicylic acid, sulphur, iodine, chrysarobin, benzoic acid, and mercury. One of the most widely used ointments is one suggested by Whitfield of England:

Salicylic acid	2
Benzoic acid	4
Lanolin	ad 30

The combination suggested is a very rational and effective antizymotic application; yet I feel that in many cases, used blindly by the general practitioner, without proper consideration of the clinical stage of the disease and the type of case, it has proved ineffective and at times even harmful. Seven per cent. of salicylic acid and fourteen per cent. of benzoic in chronic keratotic cases may not be strong enough; on the other hand, in hyperacute vesicular and dyshidrotic cases it may prove highly irritating.

I believe that any set formulæ or fixed doses are inadvisable in a dermatosis like trichophytosis, which presents such a variety of clinical types and so many grades of intensity of inflammatory processes. Set formulæ should be given only with specific indications for a certain type or stage of trichophytosis. I believe that the individualization of dose is more important than the selection of a certain drug. For this reason I have no preference for any individual or combination of antizymotic drugs but use all of them singly or in combinations in various cases.

The general principle of dermatological therapeutics, to start from soothing applications and low doses of irritating drugs and gradually increase the strength of applications as the condition approaches the chronic and sluggish stage, can be taken as the basis of the therapeutic control of trichophytosis. After each acute reaction produced by active treatment the parts should be given a rest until the irritation subsides.

ULTRAVIOLET LIGHT

One of the latest and most valuable therapeutic agents in the treatment of trichophytosis is the ultraviolet light emitted by the water cooled quartz lamp. The ultraviolet light has been proved clinically and experimentally to be a powerful germicide and antizymotic. I consider it an ideal treatment, not only on account of its high antizymotic quotient and the perfect cleanliness and comfort of the treatment, but also because of the very important quality of even diffusion of the rays over the surface of the parts exposed to light.

This even diffusion of the rays over the surface allows a perfect and thorough sterilization of any part of the skin and a thorough destruction of individual mycelia and spores that may have escaped an application of antizymotic ointment.

The main limitation of the clinical efficiency of the ultraviolet light is its superficial action. For this reason I combine it as a rule with antizymotic ointments which penetrate to the deeper layers of the skin. The greatest value of ultraviolet light in trichophytosis is to be found in the final stages, before the patient is discharged as cured, as the final therapeutic measure to destroy the last lingering mycelia and spores and to prevent recurrences. In my opinion a strong blistering radiation is neither necessary nor desirable. A medium or mild radiation two or three times a week is most serviceable. Attention to the minutest details in handling cases of trichophytosis and personal supervision by the physician at regular intervals, as well as regularity and persistence on the part of the patient, are conditions *sine qua non* for successful results. Daily bathing in hot epsom salts solution before application of the ointment is very helpful in promoting the penetration of the drug into the deeper layers of the skin.

The x ray, advocated by some writers, has, in my opinion, a very limited field of usefulness in trichophytosis. The x ray has no bactericidal power, but it may be useful on account of its absorptive and alterative effects in eczematized, infiltrated and keratotic types.

PROGNOSIS

Speaking generally the prognosis is good. The large majority of cases clear up in two to four months; a good many require not less than six months, and a few exceptional cases, mostly of the squamous and keratotic types, may require a year and over.

SUMMARY

In conclusion, I wish to emphasize the following points:

1. Trichophytosis in all its various clinical types presents a serious problem because of its enormous prevalence and wide dissemination.
2. Clinical morphological data are of equal practical importance with bacteriological findings in the diagnosis of trichophytosis.
3. The various clinical types of trichophytosis present definite morphological characteristics which enable us to make clinical diagnosis in an overwhelming majority of cases.
4. A bacteriological positive diagnosis is conclusive, but the negative does not invalidate clinical diagnosis.
5. Dyshidrosis is a distinct clinical entity, though dyshidrotic skin is more susceptible to trichophytic infection than the normal.
6. Bacteriological diagnosis is desirable for completeness of the scientific records but it is not absolutely necessary for clinical purposes and can be dispensed with in a large majority of cases.
7. The differentiation between eczematoid ringworm and dyshidrosis and eczema can be made on clinical data alone in a majority of the cases.
8. Treatment of trichophytosis should be individualized according to the clinical type and stage of individual cases.
9. Proper doses of an antizymotic application is more important than the selection of a certain drug.
10. Ultraviolet light is an important addition to our armamentarium in the clinical control of trichophytosis.

Coffee and Tea Drinking Among Children

The Results of a Questionnaire to Medical Specialists

ROBERT ROY IRVIN, Ph.D.
Pittsburgh

INTRODUCTION

The medical profession has long disapproved of the use of tea and coffee by children, and hygienists are constantly pointing out the dangers of these beverages for the young. It is nevertheless a fact that great numbers of American children are addicted to the tea and coffee habit. Numerous surveys of school children and children of preschool age have shown this to be true.

Though much information on the subject may be found in the published reports of investigations into the dietary habits of children, yet it seemed worth while to go directly to pediatrists and such other specialists as possess firsthand knowledge in matters of child hygiene and question them on the prevalence of the tea and coffee habit among children, and especially to learn from them whether educational measures against the habit are in order, and whether tea and coffee, or any other hot drinks, are allowable or necessary for children. Such information was sought by means of the questionnaire. Questions along the lines described were prepared and sent by letter to, 1, all American pediatrists and, 2, to a select group of other persons who are in positions to have dependable knowledge on the subject.

Before entering upon the discussion of the questionnaire and the results obtained from it, it is appropriate to outline briefly the results of other investigations that throw light upon the extent of the use of caffeine containing drinks by minors. The prevalence of tea and coffee drinking among children is amazing to one who is unaware of the facts in the case.

The United States Public Health Service in 1916 made an investigation (1) of rural school sanitation in Porter County, Indiana. This study also included an inquiry into the diet of the school children. It was shown that 1,277 children, or fifty-seven per cent. of the number examined, used coffee for breakfast. Incidentally, only fifteen per cent. of the children questioned reported that they had milk for breakfast. The report mentions further that the breakfasts of a number of children were deficient and that coffee or tea was a prominent constituent of such meals. At Gary, Indiana, in 1922 the Children's Bureau of the United States Department of Labor (2) found that, of the several thousand children of preschool age which were studied by the Bureau, over two thirds had coffee regularly, and that forty per cent. had it more than twice a day. Of children of foreign born parentage, over ninety per cent. drank coffee. Seventy-five per cent. of the children of Polish parentage used coffee two or more times a day.

Dr. George T. Palmer, director of research of the American Child Health Association, has recently (1924) reported (3) the results of a survey conducted by the association in eighty-six cities of the United States, whose populations lie between forty thousand and seventy thousand. The survey covered approximately thirty-five thousand fifth grade school children, whose average age was eleven years. Thirty-nine per cent. of these children drank one or more cups of coffee a day and six per cent. drank more than two cups. In the published report of this investigation, Dr. Palmer says that coffee and tea interfere with milk drinking. According to him, "The child that drinks two or more cups of coffee consumes less than a quarter of a pint of milk." The conditions uncovered by the American Child Health Association are without doubt representative of those prevailing throughout the whole United States and indicate the seriousness of a widespread habit that is rightly condemned by child specialists and child hygienists everywhere.

Other investigations also have thrown light on the extent of the tea and coffee habit among children. The United States Public Health Service in 1919-1920, in the course of a study (4) of 4,076 children living in eighteen cities in Missouri, discovered that 17.4 per cent. of the children drank tea or coffee, and that of 350 children classified as undernourished thirty per cent. drank coffee. An investigation (1923-1924) of the nutrition of children at Hagerstown, Maryland, disclosed the following facts: Of 267 children attending nutrition clinics, 34.1 per cent. drank coffee daily, and 21.3 per cent. occasionally; 16.5 per cent. drank tea daily, and 22.5 occasionally. Of fifty preschool children, fourteen per cent. used coffee daily, and six per cent. occasionally; four per cent. drank tea daily, and fourteen per cent. occasionally (5). A survey of 15,000 school children in San Francisco revealed the fact that about fifty-six per cent. of them were coffee users (6). Some years ago C. K. Taylor (7), a psychologist, made a study of 464 school children with the intent of discovering the effect of coffee on their school work. Seventy-one per cent. of them were found to use coffee to the extent of one or more cups a day. Commenting on the influence of coffee upon the school activities of the children, this investigator states: "In all it might be said that there were lower and lower grades for lessons as the amount of coffee taken each day increased. For instance, those drinking four or more cups per day averaged 63.8 for their lessons, a very great difference from the 73.4 of these drinking no coffee."

These data are sufficient to demonstrate that no insignificant proportion of our children are addicted to a habit that is distinctly harmful and of no benefit whatever, according to medical testimony. The tendency of coffee and tea to crowd out milk in the diet of children has been referred to. This result alone should be sufficient to ban their use by the young. As the result of an extensive investigation of the use of milk among a large number (7,738) of children, Miss Bernice C. Reaney (8) recently found that 38.5 per cent. of the children were coffee drink-

ers and that fifty-eight per cent. of those who used coffee did not drink milk. These figures show the effect that coffee has in displacing milk in the diet of the child. But it is to be remembered that physicians, almost without exception, hold coffee *per se* to be harmful for children because of its injurious effect upon the nervous system.

QUESTIONNAIRE TO PEDIATRISTS

Obviously, if reliable information relating to the diet of children is sought, one turns to the child specialists. It seemed highly desirable to obtain the opinions of a large number of such specialists regarding the status of coffee and tea and other hot drinks as beverages for children and regarding the desirability of renewed efforts in pointing out the harmfulness of such an uncalledfor stimulant as caffeine in the young. For this purpose, a questionnaire was prepared and sent to all members of the national and sectional pediatric societies of the United States. The total membership of these societies is 621.

The questions asked and the analysis and discussion of the answers received will be given in following sections.

Of the 621 questionnaires sent out, 292, or forty-seven per cent. of the total, were answered. As almost one half of the pediatrists responded to the questionnaire, their opinions as expressed by their answers may be considered representative to a fairly accurate degree of the views of American child specialists. This assumption is unquestionably justified in the case where answers to a question are almost unanimously the same. About three fourths of the returns were signed.

Question No. 1: Extent of Coffee Drinking Among Children. Have you observed in your community any considerable proportion of mothers who permit their children to have tea or coffee?

One hundred and eleven physicians, or thirty-eight per cent. of the number who made returns, reported that they had observed no considerable proportion of children using coffee or tea in their communities. Seventy-four, or twenty-five per cent., said that coffee and tea drinking by children was quite common among the working classes, the ignorant, and foreigners. Twenty mentioned that coffee and tea were used only slightly by children in their respective communities. A number of physicians, who evidently had given the matter of the tea and coffee habit of children more than passing attention, gave estimates of the extent to which, in their opinion, the habit prevails. It is of interest to note that such estimates indicate that fifty per cent. or more of children in general are addicts. These data are in concordance with the findings of the surveys previously mentioned. Of the few doctors who commented upon the increase or decrease of coffee and tea drinking by children, the majority believed that the habit was waning. As only a few discussed this matter, no safe conclusions can be drawn concerning it.

The replies to question No. 1 indicate a considerable divergence of opinion among pediatrics regarding the extent of the coffee and tea habit among children. This state of affairs is rather remarkable in view of the fact that statistical studies have uniformly shown that rather large percentages of American children, especially children of school age, drink one or more cups of coffee or tea daily. It is probably true that child specialists, serving a restricted group of wealthy patrons, do not come in contact with the socalled lower classes and are therefore not well informed regarding the dietary habits common among these classes. The results of a questionnaire to public health officials and public welfare workers, which will be discussed later, agree better with the findings of the surveys mentioned in the introduction with respect to the extent of the tea and coffee habit among children than do the opinions expressed in the answers of the pediatrists.

Question No. 2: Are Educational Measures Called For? If so, do you consider the practice of sufficient extent to warrant special educational measures?

Over fifty per cent. of the answers to the second question were favorable to the proposition that special educational measures against the use of tea and coffee by children are warranted. A few physicians (eight) held that sufficient steps along this line are being taken at the present time, and still others (eleven) believed that instruction of this sort should be left in the hands of existing agencies. A considerable number (thirty-seven) did not answer this question. It is suggestive of the disapproval with which child specialists regard the use of such stimulants as tea and coffee by children that, though a large proportion of those who answered the questionnaire have reported that they have not observed any considerable number of children drinking tea and coffee in their communities, over one half of those who answered question No. 2 are in favor of educational measures against the use of these beverages by children.

Question No. 3: Essentiality of a Hot Drink for Children. Do you believe that a hot beverage is essential in the diet of school children during the winter months?

Less than one fourth of the physicians who answered question No. 3 are of the opinion that a hot drink is essential to the diet of children. Over one hundred stated, however, that a hot drink or hot liquid foods are desirable for children and many of them mentioned that such hot liquids as hot milk, cocoa, chocolate and soups are advantageous to children.

Question No. 4: Permissibility of Tea and Coffee for Children. Do you believe that tea or coffee should be allowed in the diet of children?

Pediatrists who responded to the questionnaire were practically unanimously opposed to the regular use of tea and coffee by children. Only one physician answered this question unconditionally in the affirmative. A number held, however, that the beverages have some medicinal and therapeutic value. Twelve mentioned that weak tea or coffee may sometimes be employed in the treatment of ill or convalescing children. A little coffee or tea as flavor for milk was also referred to. Nine doctors objected to the use of tea and coffee only by children under the age of adolescence. Three were of the opinion that weak tea and coffee are harmless for children.

THE QUESTIONNAIRE TO CHILD HYGIENISTS, PUBLIC HEALTH OFFICIALS, CHILD WELFARE WORKERS, AND EDITORS OF MEDICAL JOURNALS

A limited number (fifty-four) of the questionnaires forwarded to pediatrists was later sent to cer-

tain other specialists who were presumed to be in positions that would afford unusual opportunities for observation on the dietary habits of large numbers of children. In this group were public health officials, child welfare workers, child hygienists, and editors of medical periodicals. Of the fifty-four questionnaires sent out, twenty-four, or forty-four per-cent., were executed and returned. The information obtained from these returns did not vary greatly in nature from that gained through the answers to the questionnaires returned by pediatrists, except as to extent of the tea and coffee habit among children. The recipients of the second questionnaire apparently are better informed on the prevalence of tea and coffee drinking by children than are pediatrists. This is indicated by the better agreement of the answers of the former with statistical studies on the dietary habits of large groups of children.

DISCUSSION

The discussion of the answers to the questionnaire returned by specialists in child hygiene and in child welfare is given below.

Question No. 1.—Twelve persons indicated that they had observed considerable numbers of children using coffee and tea; five indicated that the habit was not prevalent in their opinion. Two stated that the drinks were used quite commonly by the children of lower classes, but to a less extent by children of the educated classes. One hygienist believed that only a few children use tea and coffee, and another remarked that the habit is on the decrease. One return gave valuable statistical data on the subject. These data were in close agreement with published information. Two specialists did not answer this question.

Question No. 2.—The majority of the persons who answered question No. 2 favored educational measures against tea and coffee drinking by children; only six indicated that they felt that steps in this direction were unnecessary. One stated that educational measures would be justified, provided the instruction could reach the classes that needed it. One official in the United States Public Health Service expressed the belief that the practice of tea and coffee taking by children was on the decline. Three persons who made returns did not answer this question.

Question No. 3.—Eight unqualified answers to question No. 3 were in the affirmative; seven were in the negative. Six persons were of the opinion that a hot drink was desirable or beneficial for children, some stated that hot water, cocoa, hot milk, etc., were of value in the child's diet. One said that a hot drink was essential whenever there were no other hot foods available. In one return the question was not answered. The answers received to this question indicate that the majority look with favor upon a hot drink or hot liquid foods for children, but that only a smaller proportion believe that such drinks are essential for children.

Question No. 4.—All answers (twenty-four in number) to question No. 4 were in the negative. One physician of prominence was not convinced that tea and coffee had been proved harmful for children, yet he was inclined to play safe and prohibit these beverages for minors. Several pointed out in their answers to this question that tea and coffee minimized the use of more nutritious beverages.

Here again we have evidence of the practically universal opposition by those in positions of authority in matters of child hygiene to the practice of allowing tea or coffee as a constant item of the diet of children.

CONCLUSIONS

Despite the fact that a considerable proportion (thirty-eight per cent.) of the pediatrists who responded to the questionnaire stated that they had not observed any considerable number of children drinking tea and coffee in their respective communities, those who had given the matter special study, as well as a number of child hygienists and public health workers, all reported finding an astonishingly large percentage of children to be coffee addicts. These observations agree with those of numerous reports of studies of the diets of school children.

The majority of all those who answered the questionnaire are of the opinion that educational measures against the practice of tea and coffee drinking by children are desirable. A not inconsiderable number expressed some doubt as to whether instruction would be effective in reaching the classes that need it most.[1] Many pediatrists who reported that they were unaware of the use of tea or coffee by any considerable number of children in their communities were nevertheless disposed to look with favor upon a special campaign against the habit of tea and coffee drinking among children.

On the basis of the results of this questionnaire, it appears that a hot drink, even during the winter months, is not considered strictly essential to the diet of children by the majority of child specialists and child hygienists. But many hold, however, that hot drinks and hot liquid foods, such as hot milk, cocoa and soups, are often beneficial and desirable. Some pointed out that such hot liquids are especially called for when the child is compelled to take a cold meal.

A practically unanimous opposition to the allowing of beverages containing caffeine to children was found. This is not at all surprising, because the medical profession has for years put itself on record against such a misuse of our most common stimulant. The replacement of more nutritious beverages by coffee or tea was often referred to as a reason against its use. Undoubtedly coffee and tea beverages have no standing whatsoever among those competent to pass upon the dietary of the young.

In all, the findings of this questionnaire confirm the results of other surveys covering the use of stimulants by children. A large proportion of our children are addicted to a habit which is not only of no benefit to them and which interferes with their consuming an adequate amount of milk, but which also is of distinct harm to them, according to prevailing medical opinion.

[1]It is of interest to note in this connection that an unpublished report of an effort to reduce coffee drinking by school children in San Francisco states that a three months campaign (March 1 to June 1, 1923) against coffee resulted in a decrease of from 52.2 per cent. to 22.1 per cent. of children using coffee. These children attended twelve different schools and were 7,390 in number. In twelve other San Francisco schools (8189 children) which were not included in the campaign, 60.5 per cent. of the children were found to be constant users of coffee during the same period. The second set of schools was essentially comparable to the first in all respects. (Personal communication from Prof. A. A. D'Ancona, Deputy Superintendent of Schools, San Francisco, Cal.)

Instruments, Apparatus, and Clinical Notes

Oral Method of Cholecystography with Tetraiodophenolphthalein

Preliminary Report

VICTOR KNAPP, M.D.

New York

Since Graham and Cole (1) introduced the technic of röntgen visualization of the gallbladder by means of radiopaque salts, some further experimental and clinical studies have been published by Carman and Counsellor (2), Whitaker and Milliken (3), and others. Of the various halogenated tetraphenolphthalein compounds that have been used, it has been found that sodium tetraiodophenolphthalein is best, both for the oral and intravenous routes. A smaller dose of this dye is required, the reactions are uncommon, and when they do occur are mild, and the results are satisfactory. Whitaker, Milliken, and Vogt (4) were the first to give this dye orally, but Menees and Robinson (5) used tetrabromphenolphthalein by mouth before them.

In our work in the hospital we have used sodium tetraiodophenolphthalein in enteric coated capsules of five grains each, employing forty grains for each patient. Both the keratin coated and salol coated capsules have been utilized, and no difference in results has been noted.

To get a clearer understanding of what is to follow let us review the course that the dye takes when given by mouth. Because of its coating the capsule is not affected by the gastric juice, but is dissolved in the intestine, where the dye is liberated and absorbed. Then it is carried by means of the portal vein to the liver, where it is removed from the blood by the hepatic cells. Then the dye is excreted into the bile and reaches the gallbladder by way of the hepatic and cystic ducts; and then reaches the intestine again by way of the cystic and common bile ducts. It may be inserted here that when the dye is given intravenously it reaches the liver by way of the systemic circulation, and then follows the same course as the orally administered dye. Because of the radiopacity of the dye, a shadow of the gallbladder is produced when dye stained bile is present there. From the presence or absence of the shadow of the gallbladder, and from its contour, we make our deductions. It must be remembered that in using the oral method the condition of the gastrointestinal tract must be considered, and also we must look for undissolved capsules in the small and large intestines. Of course, the state of health, if we may term it such, of the liver is to be considered in both the oral and intravenous routes.

In our consideration of the normal, or rather what at the present time is considered as normal shadows, we will assume that there is no pathology in either the gastrointestinal canal or in the liver. Our procedure with a patient is as follows: The evening before the examination at five o'clock, the patient is instructed to eat a plate of vegetable soup, a baked potato and butter, some bread and butter, and some tea with milk or lemon and sugar. This serves to empty the gallbladder. After this the patient is not to eat anything, although he is allowed to drink water freely. At nine o'clock the same evening he is to begin taking the capsules; taking two every fifteen minutes until eight have been taken. As stated above the capsules contain five grains each of the dye. Before retiring the patient takes an enema. It may be added that the need for the enema is probably not urgent, for it has been observed that without it, many cases give satisfactory results. But for the sake of uniformity in technic, this has been included in the instructions. Now at nine o'clock the next morning the patient reports for the first röntgen examination without having had any breakfast. What has happened during these twelve hours is digestion of the capsules and the absorption of the dye, then its excretion into the bile. So that we expect that the bile now present in the gallbladder is dye containing and will cast a shadow.

This observation, then, should reveal a regular pyriform shadow of the gallbladder, which appears as a uniform white shadow on the plate. This shadow is similar to that obtained from the barium filled stomach, but of course not as dense. After this examination the patient is not to eat anything for another four hours, at which time another plate is taken. This shadow of the gallbladder should be of equal or of larger size as that seen at the twelve hour interval. The patient now has his regular noonday meal and reports for another observation three to four hours later. At this time the gallbladder shadow should be smaller in size than at the other two periods, or else be entirely absent. The patient continues with his meals as usual now, and returns for another observation the next morning, which is thirty-six hours after ingestion of the capsules. This plate should show no shadow.

To recapitulate: The theoretically normal person should show a gallbladder shadow in the twelve hour observation, which is both uniform in outline, and of equal density throughout; in the sixteen hour plate the shadow should be of equal or greater size; in the nineteen or twenty hour plate the shadow should be smaller than either of the other two, or be entirely absent. In the thirty-six hour plate there should be no gallbladder shadow.

Thus far our series of cases numbers thirty-six. These are unselected; their ages range from twenty-one to fifty-five with an average age of forty; all but one are women; all of the women are married, with two exceptions; and all the married women have borne one or more children with the exception of

four. About half of them are obese, and all of them complain of gastrointestinal symptoms. None of them have any clinical evidence of liver disease which would contraindicate the use of the dye; and none of them have delayed gastric emptying which might interfere with the solution of the capsules. In no case is there any common duct obstruction which would interdict the administration of the dye. One of the cases has mucous colitis, but since the absorption of the dye probably does not take place to any extent in the colon, this condition cannot be said to interfere with the efficiency of the test. So taken all in all, this series should offer no obstacle to the successful demonstration of this method.

Nine cases, or twenty-five per cent., failed to give any shadow of the gallbladder. Of these, only one was clinically diagnosed as gallbladder disease, and in this case there were suspicious shadows of calculi in one of the plates. In these nine cases, four showed the presence of from one to six undissolved capsules; so that we are confronted with the question of whether or not enough of the dye was absorbed from the intestine to cast a satisfactory shadow. In this connection it is interesting to note that Oakman (6) took two normal gallbladders, each attached to its adjacent block of liver tissue, removed at autopsy, and tied off the cystic ducts. Then he radiographed them under a four inch water phantom, and obtained no shadow. He then injected one gram of aqueous solution of tetrabromphenolphthalein into one of them, and twenty-five hundredths of a gram into the other. Under similar conditions, he radiographed the gallbladders again. The first one showed a clear shadow, and the latter a shadow that was barely discernible. He ventures the statement that perhaps some cases need hardly more than one gram of absorbed dye to be visualized. Our experience has been that in one case in a fairly obese woman, good visualization of the gallbladder was obtained, when only three of the capsules, or only fifteen grains of the dye, were absorbed. But then we are using tetraiodophenolphthalein, and less of this dye is needed for satisfactory results, than of the bromine compound. So it remains to be determined by further study just how much dye is necessary to cast a shadow. Parenthetically it may be added that the amount of absorbed dye is meant.

Thirteen of the thirty-six cases, or thirty-six per cent., were definite clinical cases of gallbladder disease. Of this number five gave a normal series of shadows, one of which was operated upon, and stones were found. Of the other eight, three gave positive evidence of calculi, and this was proved by operation. One showed a displaced shadow of the gall bladder, that is the fundus seemed to be held up under the liver edge; which would indicate pericholecystic adhesions. Two showed suspicious shadows of calculi. Two gave evidence of cystic duct obstruction, or obstruction in the neck of the gallbladder, in that the gallbladder shadow persisted after the thirty-six hour examination.

Three cases which were not gallbladder disease clinically gave signs suggestive of cholecystic pathology; that is, the shadow persisted after the thirty-six hour observation. At this point it may be mentioned that the question of reabsorption of the dye from the intestine must be considered, with subsequent revisualization of the gallbladder, if we may term it such. The discovery that the oral route might be successfully employed was made during the rou-

FIG. 3.—Plate taken nineteen hours after the administration of the dye. The arrows point to the filled gallbladder. Note the diminution in size as compared to Figs 1 and 2.

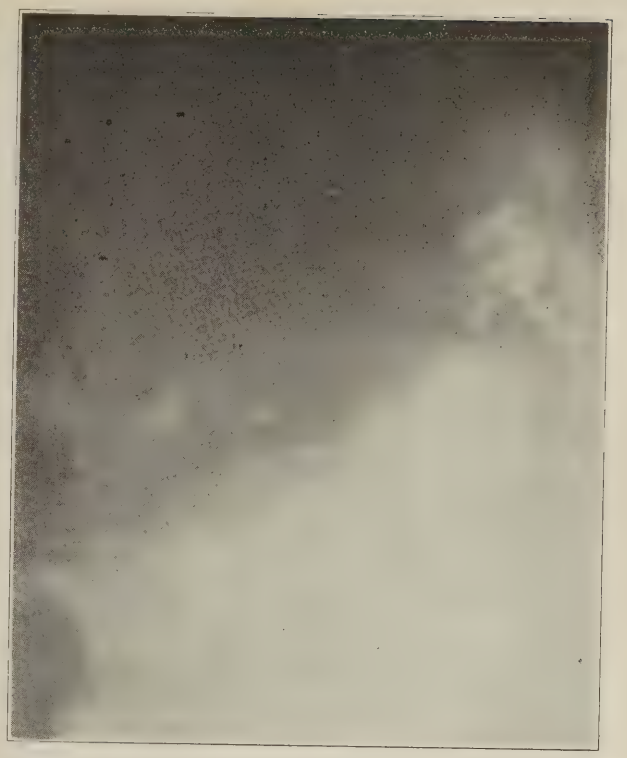

FIG. 4.—Plate taken thirty-six hours after the administration of the dye. Note the entire absence of a gallbladder shadow. Compare with FIG. 3.

tine gastrointestinal study of patients who were given the dye intravenously (7). It was noted that the gallbladder shadow which was absent twenty-four hours after the intravenous injection, reappeared in seventy-two hours. This was rightly ascribed to the reabsorption of the dye from the intestine after its excretion into the intestine by way of the bile. Therefore with a case of a persistently filled gallbladder this factor must be considered. But the answer probably will not come from a reading of the plates alone. A careful consideration of the clinical picture of the case, the signs of gallbladder disease obtained from a routine röntgen ray examination of the alimentary canal, will also have to be considered before a conclusion is drawn from the employment of the dye visualization of the gallbladder.

All of the other cases showed normal shadows. In a number of the cases the ileum, the cecum, the ascending, and sometimes the transverse colon were seen to be outlined by the dye. It is in cases of this kind where the question of reabsorption of the dye presents itself for consideration. Also the presence of undissolved capsules must be ascertained. Too, it is to be remembered that the plate takes in only the right half of the abdomen, or less, and that there may be both undissolved capsules and unabsorbed dye in the small intestine and the colon, which occupy the left half of the abdomen. This brings us to the necessity of emphasizing the importance of fluoroscoping each case before the plate is taken to determine, how many, if any, capsules remain undissolved; or if any dye stained intestinal coils can be identified. This has not been done in our series, but will be done hereafter.

In no case were we able to detect the gallbladder fluoroscopically in our cases which were fluoroscoped.

It has been noted that the liver shadow becomes more visible after the dye is taken, and less visible as the dye is excreted. This observation may or may not be of value, but it can be depended upon because the technic of taking the pictures does not vary. Of course, the sharper liver shadow is due to the presence of the dye in this organ. We have had no real reactions from the dye. Two patients complained of intense nausea, but nothing else. The intravenous route has not been employed in any of the cases. It is suggested that in doubtful cases the results should be checked up by giving the dye intravenously.

The question whether or not this method will increase the accuracy and frequency with which calculi are demonstrated, naturally arises. At this time it is not possible to answer this. But it is to be remembered that while without this test we depend upon a positive shadow of a calculus for a diagnosis, with the dye the presence of calculi are sometimes manifest by negative shadows. That is, the gallbladder is seen outlined with the dye stained bile, except in the portion occupied by the calculi. It is also well to keep in mind that the dye stained bile may overshadow an otherwise visible calculus, hence the advisability of taking a röntgengram before the dye is administered. Before the advent of the dye, a calculus which contained a sufficient amount of calcium only cast a shadow. The proposition now arises whether or not the amount of iodine present in the dye stained bile might not overshadow the calcium containing calculus which would otherwise be visible. This is another question which will have to be answered as more experience accumulates, and more patients who have had the dye-test have been

operated on. We had one case which showed a normal series of shadows, and which proved to be cholelithiasis upon operation, as mentioned above. It has been suggested that calculi which have rough surfaces will cause the dye stained bile to adhere to it, and thus an annular shadow will be produced.

As experience is gathered, we will learn what the normal gallbladder is, what its variations are, and what positions it may assume. That pericholecystitis may be diagnosed with accuracy is selfevident, if a distorted shadow is seen.

Reviewing the technic of the oral administration of the dye, we find that there are many drawbacks to its use. There is a great factor of uncertainty in the amount of dye that will reach the blood stream, and hence the bile. Then there is the intelligence of the patient to be considered in carrying out the instructions. And then there is the important matter of having the capsules in which the dye is placed, uniformly and entirely coated. The condition of the gastrointestinal tract must be considered, in order that we may be certain that there is no pathology present which would interfere with digestion and absorption of the dye. We must see that no liver disease is present, and that there is no obstruction in the common duct.

CONCLUSION

Withal we have a method that will prove more and more instructive, as the entire problem is better understood. There is no doubt that if we are able to visualize an organ, we can better tell what that organ can do or is doing. Probably, we are in the same state of uncertainty regarding what is and what is not a normal series of gallbladder shadows, as we were not so many years ago regarding the stomach. When that organ was first seen filled with an opaque salt, every variety of abnormality was read into perfectly normal radiographs. And it was only with the repeated application to the study of the various manifestations exhibited by gastric röntgengrams that we have arrived at the definite knowledge we now have of the stomach. So it will probably be with this method of gallbladder visualization.

That the oral method is and will be the method of choice over that of the intravenous route, there can be little doubt. The former is safe, it is an office procedure, there are no reactions of any moment, and it does not necessitate any real interruption in the usual routine of the patient's day. Its limitations are appreciated, but these will be erased as we learn more about it. Its simplicity recommends it. The intravenous route has yielded ninety-five per cent. positive diagnoses (7) in the hands of one observer, and should be employed in doubtful cases.

No discussion of the technical problems involved in the taking of the radiographs have been included, for it is out of place in an exposition of this kind.

A Contribution to the Technic of Urography

S. R. WOODRUFF, M.D.

Jersey City

The collaboration of the x ray department of a hospital can be used with marked benefit in urography by immediate development of the films before the cystoscope or catheters are removed from the patient. In this way the urologist is able to look over the film and determine its value—whether the proper diagnostic data has been obtained—or—if this be lacking, the apparent error is easily observed and another exposure made under the proper conditions. The waiting time is hardly over six minutes and the information obtained invaluable. It is distinctly mortifying after cystoscoping a patient, catheterizing the ureter, injecting the contrast substance and making several exposures to find the next day that the urograms have been of no value and that the procedure must be repeated. This is often made impossible by the condition of the patient, or a refusal to undergo the examination again, or the danger of over exposure with the x ray.

The simple procedure of immediate development, and observation of the film by the urologist before removing the cystoscope from the patient, is a marked advance in urography.

In removing the contrast substance from the renal pelvis and ureter after a urogram much time is saved by lowering the injection receptacle below the level of the kidney and syphoning back the fluid rather than disconnecting from the catheter and allowing it to drip out.

Remarkable Adhesions of the Large Intestine

DOUGLAS REID, M.B.

Cambridge, England

The following condition found by me recently, but only after death, seems nevertheless of enough surgical interest to warrant a note. It occurred in a strongly built middleaged male. The left lobe of the liver, unusually large, projected extensively downwards in front of the stomach. Indeed it reached as low in the abdomen as the right lobe, which was normal in size, and almost completely covered the stomach in front. Only adjoining its pyloric end was the stomach exposed below a deeply concave central portion of the lower edge of the liver formed by both lobes.

Its pyloric part, unusually attenuated (possibly a correlated variation), was continued into a duodenum whose terminal (fourth) part (ascending portion of pars inferior) was practically absent.

The duodenojejunal flexure (Fig. 1) lay in front of the left border of the aorta quite two inches below its usual (transpyloric) level. It still held contact, however, with the lower border of the pancreas whose body had been flattened out at the expense of the whole of its inferior surface.

Fig. 1.—A, duodenum; B, round ligament here in middle line; C, stomach; D, duodenojejunal flexure; F, transverse colon; G, descending colon; H, cecum; I, crest of ilium; J, border of great omentum; K, iliac colon; L, ileum (cut); M, pelvic colon; N, recti muscles, cut and reflected; O, pelvic brim; P, spine of ileum; Q, mesentery (cut); R, crest of ileum; T, ascending colon; U, space; V, cut wall of abdomen; W, jejunum (cut); X, great omentum; Y, right side of liver. The root of the mesentery is represented by a thick interrupted line. This drawing was made from a tracing and taken on a glass plate laid over the actual parts.

The cecum—of infantile type—lay inverted in a quite unusual position (the concavity of the splenic flexure). It occupied chiefly the left lumbar region. Covered in front by the great omentum, it was in contact with the left part of the transverse colon as well as with the descending and iliac colons, to all of which it adhered firmly.

These parts formed a loop, open downwards, almost completely encircling the cecum and holding it securely in position. The splenic flexure lay considerably below the normal level. The beginning of the colon as well as the terminal part of the ileum passed upwards to the cecum through the space left below between the limbs of this colic loop. Thus the colon descended from the cecum instead of ascending as normally. It then crossed the middle line over the first sacral segment to reach the front of the right common iliac artery. Here it turned upwards as a very narrow ascending part which crossed the iliac crest and came into contact with the right kidney.

Small intestine completely covered the cecum and colon up to this point, and also lay in a considerable space to the right of the ascending part which it completely separated from the lateral wall of the abdomen and right lobe of the liver. I have never before seen the ascending colon so completely buried behind the small gut and so completely separated by it from the lateral wall of the abdomen and from the liver. Posterior gastrojejunostomy would have been impracticable for the transverse colon lay in contact with, and fused to, the posterior abdominal wall.

Fig. 2.—A, root of mesentery; B, terminal part of ileum, adherent portion; C, duodenum; D, mesentery; E, right (descending) limb of pelvic colon; F, ileum ("free" part); G, cecum. Adult male. The pelvic colon forms a large intraabdominal loop fixed permanently in this position by adhesions. The mesentery, indeed, has fused down to the right (descending) limb of the loop, whose summit touches the duodenum, as is quite common in the fetus. Thus the mesentery arises from the duodenum as normally, but below this from the pelvic colon, and not at all from the posterior parietal peritoneum. The ileum in its terminal few inches, however, is bound down directly to the peritoneum over the right psoas. The nature of these fusions is suggestive of the operation during fetal life of the genitomesenteric fold of peritoneum described by me. This, provided it is not itself obliterated by the pelvic colon (see e.g. *Proceedings of the Royal Society of Medicine*, London, 1914, Vol. VII, may sometimes pull the mesentery down over this preceding even cecal descent) in addition to fixing the terminal part of the ileum. The fold may then itself become fully obliterated. I have noted a similar condition in two other adults. The strip of white paper extends between the ascending and pelvic colons.

Like the great omentum it had no relation to the anterior abdominal wall for both were completely concealed from view behind coils of small intestine.

Normally, *"des anses intestinales couvrent quelquefois"* the anterior face of the transverse colon.

It adhered to the second part of the duodenum, commencement of the jejunum and head of the pancreas. To the left of this its mesentery was fused down over the duodenojejunal flexure, left psoas, kidney and the upper part of the cecum to which, as already noted, the transverse colon also adhered directly.

Thus it was completely deprived of a mesentery, a condition I have never seen before (in over one thousand adult bodies examined). Moreover, the transverse colon adhered to the mesentery of the small intestine along the whole length of the abnormally placed root (thick interrupted line in illustration). The (ascending) colon which passed from the cecum across the middle line also adhered to the right (here inferior) surface of the mesentery along the line of its root. The left part of the mesentery was thus wedged in between, and adhered to, two usually completely separated parts of the large intestine, both close together and securely fixed to the posterior wall of the abdomen.

DEVELOPMENTAL FUSIONS

I have shown that fixation combined with pressure are the two essential causes in the formation of developmental peritoneal adhesions. The unusual fixation of the mesentery and cecum between parts of the large intestine was obvious in this case.

I have now seen examples in the adult of (developmental) fusions of the mesentery to all the different parts of the colon (ascending, transverse, descending (at its lower part) iliac and pelvic). In the case of the pelvic colon I have seen, e. g., a loop which apparently had retained its fetal position in the abdominal cavity through the descent of the mesentery and its fusion down over it. Indeed, below the duodenum the mesentery arose entirely from the right limb of the pelvic colon and not at all from the posterior abdominal wall. I have several photographs showing these conditions which must be of interest in connection with operations such as freeing the colon from adhesions, inguinal colotomy and excision of the rectum. In other papers I have dealt with the

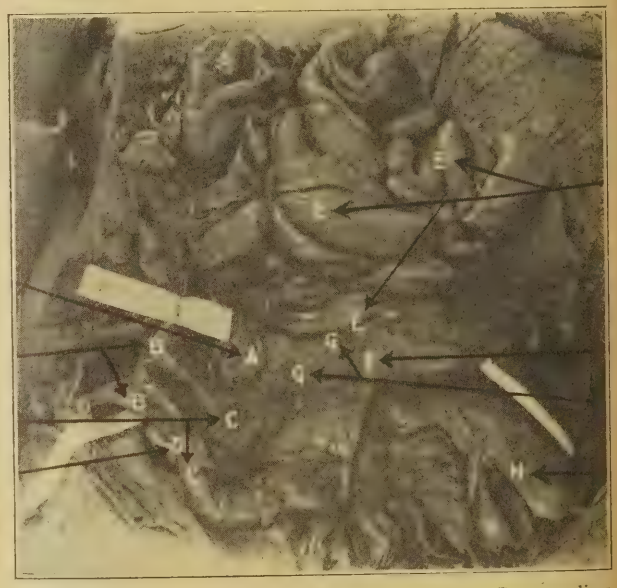

Fig. 3.—A, terminal part of ileum, pulled upward; B, appendices epiploicæ; C, pelvic colon; D, small part of cecum; E, small intestine pulled upward; F, colon crossing bifurcation of aorta; G, mesentery; H, left psoas major muscle. I have shown that the lower part of the mesentery of the terminal intestine (Jonnesco)—the part of the large gut between the splenic flexure and the anus, has a tendency in the fetus to rotate toward the right, so that its originally right (instead of its left) surface becomes posterior. This may result in the terminal intestine crossing in front of the aorta to reach the right iliac fossa, and the inferior mesenteric artery correspondingly shifts its origin on the aorta toward the right. When the root of the mesentery descends, with the formation of the ascending colon, to become oblique, it is thus brought up against the colon in this unusual position, and may fuse to or over it, especially if the colon has already become fixed. This condition is shown in the photograph of an adult male given above (I have seen it still better marked). The colon here crosses the bifurcation of the aorta and forms a loop, pelvic colon, in the right iliac fossa. This loop, which covers the cecum, is bound to the parietal peritoneum by strong appendices epiploicæ. The lower strip of white paper on the right side is insinuated under one, and another holds the summit of the loop to the right side of the abdomen. The left end of the upper strip of white paper on the right side rests on the small intestine to show the mesentery arising very largely from the upper limb of the loop of pelvic colon and from the colon just above this. In front of the ascending colon was found a wellmarked membrane formed by strong appendices epiploicæ. It is noteworthy that I found the cecum in the fetus generally adherent (to the parietal peritoneum) before its descent. This does not necessarily prevent, although it may hinder, its ultimate migration to the right iliac fossa. The ascending colon may in some such cases have a mesentery dragged out in this descent. In other rarer cases, the primitive mesocolon may of course persist.

position and form of the pelvic colon and its importance in producing in the fetus adhesions of parts against which it may press. (See, e. g., *Journal of Anatomy* of Great Britain, 1911.) These adhesions, perhaps, may be termed accidental peritoneal fusions—common enough, but unthought of, as it were, toward the support of viscera in the assumption of the erect attitude, yet no doubt of some surgical interest as I have tried to show.

In an adult I found recently a loop of pelvic colon, more than two feet in length along its convex border, lying, along with a short loop of small intestine, in the sac of an oblique leftsided inguinal hernia. As far as I know there is not another case like this on record.

Instead of going obliquely downwards and to the right, the root of the mesentery descended in the middle line in front of the aorta, and then curved abruptly to the left of the ileocecal junction. It formed a curve concave upwards. Thus the usually left and lower surface of the mesentery was in this case the left and upper; and the loop of transverse colon fitted exactly into this concavity formed by the mesentery to which it adhered. The ileocolic artery (which forms a relatively rigid bar in the fetus determining the extent of normal fusion of the mesentery) lay along the line of the root as it does primitively. It arose from the left (instead of right) side of the superior mesenteric artery as this crossed in front of the duodenum. All these conditions were undoubtedly largely due to the unusual elongation of the ascending colon, and to the persistence of an unusual portion of the left lobe of the liver.

In the course of development the root of the mesentery of the small intestine, at first horizontal, becomes oblique along with (or before in some cases) the descent of the cecum. In its passage to the left of the middle line the ascending colon naturally elongated along the line of the root, and was thus brought into firm contact with and adhered to the mesentery.

The case seems interesting, then, on account of these remarkable adhesions, and the concealed and completely buried positions of normally exposed parts —transverse colon, cecum, ascending colon, great omentum. Before this I have never seen a cecum reach into the left lumbar region.[1] Apparently also it had not at first descended to the pelvic diaphragm before turning upwards to become inverted, but had taken a short cut across the first sacral segment.

The various adhesions of the parts, including the duodenojejunal flexure, were thus practically all on the left side of the middle line. In addition to what I have indicated doubtless they were determined in part by the large size of the left lobe of the liver and its unusual projection downwards. I regard them all as entirely developmental in origin. There was no evidence to contradict this.

[1]Previously I once found the cecum in the left iliac fossa. There are thirty-six observations *"de hernic inguinale gauche* (Pujol, 1896)" The cecum *"pent faire de toute les hernies ombilicale, crurale, inguinale, et même du côté gauche."*

The Treatment and Prognosis of Intraperitoneal Adhesions

DANIEL H. BESSESEN, M.D.

Minneapolis, Minnesota

The treatment of adhesions resolves itself into preventive and curative types of therapy. These may be further divided into preoperative, operative and postoperative. Preoperative therapy stresses those methods which will secure a good postoperative recovery. In general, conditions which maintain the patient's normal processes of life will give the best results. Early operation in such infections as require surgical treatment cannot be too strongly recommended. If the preparation warrants sufficient delay the elimination of foci of infection grants respite from a possibility of a spread of inflammatory reactions from these sources. There seems to be an opinion prevalent that a highly activated alimentary tract both before and after operation will prevent the formation of cohesions. This view is misguided, however, since any such stimulus produces hyperemia with its concomitant regenerative activity and increased tendency to cicatricial production.

Since the pathogenesis of adhesions is based upon the same principles as healing, or the formation of other cicatrices, a surgical procedure performed with this in view will do much to avoid the formation of adhesions. The correct incision is one which is placed so as to interfere as little as possible with the blood and nerve supply of the parts, making it only of such size as to accomplish the purpose of the operation and progressing as expeditiously as compatible with thorough and careful work. Such an incision properly repaired using the Czerny-Lembert suture coapting a broad peritoneal surface is the best safeguard against hernia, as also against cohesions. The use of dry sponges or gauze on the peritoneum is similar to a curet: the delicate endothelial surface is roughly torn. Forcible retraction is also very damaging to tissues. It is perhaps better to use a self retaining retraction —of which R. E. Farr's represents a favorable type. During manipulation, very gentle handling of tissues with avoidance of drying or contact with chemicals —such as iodine painted skin—are attentions which render the wound much more responsive to rapid healing.

The experiments of Walthard (1) clearly demonstrate the action of drying as an endothelial injury. So on opening the abdomen, careful walling off of all areas except that which represents the field of endeavor protects the peritoneum from unnecessary exposure. Moist hot sponges are best for this purpose as well as for hemostasis. Strict asepsis, with complete hemostasis and closure of all raw areas by contiguous or transplant grafts of peritoneum or omentum constitute important steps in good surgical technic. In the use of the cautery a thorough application leaves a thick eschar of necrosed tissue under which

healing takes place with no tendency toward cicatricial attachments. A mild application leaves a raw surface insufficiently covered over with necrosis to prevent or allay this tendency. Before closing, a careful arrangement of the intestinal loops within the abdomen makes any cohesions which do form less likely to cause clinical symptoms.

Drains give rise to thick dense adhesions. As a rule, they are inserted in the presence of infection and peritonitis produces such a violent regenerative reaction as to create by itself extremely tenacious bands of scar tissue. When this is further aggravated by the presence of a foreign body there is added the final etiological factor in the production of the densest of eschar formation. The study to which drains have been subjected leaves no longer an experiment this important aid in surgery. It is recognized that gauze does not serve for drainage purposes, either alone or in conjunction with a rubber tube. A thick, heavy rubber tube is equally injurious. Thin strips of soft rubber, Penrose drains, or the Gibson tampon pack in severe infection, meet all the requirements for drainage of any field. The proper position for drains is against the abdominal parietes not into the loops of viscera. This is one of the chief advantages of the Gibson tampon drain. Postural drainage is worthy of thought following a septic operation; R. C. Coffey (2) has well demonstrated the value of turning the patient on the right side and from that position elevating him to the Fowler position, dropping all the débris into the pelvis.

The growth of adhesions is dependent upon the same principles which control the healing of a wound, by primary or secondary intention. For this reason, any effort to delay the formation of adhesions will in like manner delay the healing of the wound. Thiosinamine, phosphorus, peptone and fibrolysin are misdirected efforts to accomplish this purpose. Any introduction into the abdomen of such substances as oils, unguents, viable or nonviable grafts with the possible exception of autogenous grafts are alike all foreign substances and stimulate the peritoneum through direct trauma, chemical or physical stimulus to a greater reactive effort with the resulting thicker, denser, firmer entanglements of organs in a network of massive scar tissue.

The use of the omentum as an autogenous graft in closing upon raw areas has been experimentally introduced by Senn (3) and is highly recommended by Freeman (4). Where there is tension it is preferable to use fascia lata. Both of these structures act as hemostats and do not cause infection. A sufficient number of catgut sutures must hold the transplant in place to guard against its shifting. It should not pucker and should project over the edges of the raw surface; yet using no more tissue than necessary. The excision from the omentum is best made away from the large vessels. The chief objections to this procedure are the occasional formation of multiple foci of hepatic necrosis and the causation of gastric or duodenal hemorrhages. These complications are believed to be due to embolism arising from thrombosis of the omental vessels. They are very unusual complications and occur more frequently in men than in women. Still other objections are the loss of a useful organ and the production of a raw omental edge. The objections are overlooked, however, when one is dealing with an abdomen which possesses tremendous capacity to form adhesions in an effort—often successful—to prevent their reformation. The practice of planting the cecum or sigmoid or uterus into the pelvic regions to cover raw areas needs no detailed consideration as they are recognized important procedures under certain circumstances. Richardson's (1) technic in covering intestinal denudations by the mesentery or part of the mesentery of the denuded loop is worthy of adoption.

The best possible preventive of adhesions is good surgical technic, careful operative work with thorough closure of raw areas under aseptic conditions, leaving the patient as nearly undisturbed physiologically by the operation as can be accomplished.

Postoperative enteroclysis of five per cent. glucose or saline solutions, heat (especially dry—in the form of a light) applied over the wound, careful regulation of diet—being slow to introduce any foods which may cause any intestinal disturbance, are important early measures. Later, massage, exercise and belts may be recommended in individual cases. An excellent method of massage is the rolling of a small bowling ball around the abdomen clockwise. Administration of telatherm is very beneficial in some of these patients.

In cases which represent ill results of previous operations, where one opens up an abdomen full of adhesions, it is necessary to know before the celiotomy what part of the peritoneal cavity requires attention. The same surgical precautions must be remembered with the addition that adhesions which are not causing trouble should be left alone. Often the separation of attachments not producing clinical symptoms results in their reforming in greater number and more serious fashion with sometimes evidence of critical disease. Therefore, only such adhesions as are causing the immediate trouble should be disturbed. Special care is taken to make a correct and complete closure bearing in mind the surgical principles above mentioned. Following operation postural treatment is important as an adjunct to the prophylactic measures previously considered. At the time of operation changing the position of the patient will demonstrate more clearly the cohesions which affect the individual's health. Injecting oxygen into the abdominal cavity keeps the wall of the abdomen lifted away from the viscera while healing of each area progresses. The benefits to be derived from hypermotivation of the alimentary tract or interference with coagulation of exudations are very much questioned. There can be nothing gained by these measures except to delay the normal convalescence of the patient and even bring about other complications.

Obstruction from adhesions requires immediate surgical procedures. In septic obstruction, it is wise to perform ileostomy. It is these cases which represent the most severe picture of this type of pathology. Obstructions will frequently recur unless one can prepare the abdomen by prophylactic surgery for the return of organs to their normal positions leaving no possibility for return of this dreaded complication.

As a general rule, the patient may become adapted to the new adhesive supports within the abdomen. It is only a small percentage of patients who really complain sufficiently to attract the serious attention of

the attending surgeon: and careful physiotherapy, hydrotherapy and medications give relief to this number which constitutes probably five per cent. of the total operated cases. The patients who remain intractable to the very best of care fortunately are few indeed. There are no data as to their number in the available literature though they probably do not reach a figure higher than 0.01 per cent. of all those who complain of adhesions.

The treatment of adhesions, then, is first of all prevention by thorough, rapid, aseptic surgery in a warm room with warm moist protection of the viscera and careful hemostasis, complete closures with pneumoperitoneum, postural rest, diet, massage, exercises and abdominal belts. The prognosis in these cases is for the most part good, with the exception of a very small percentage which remain intractable to any form of treatment with recurring intestinal obstruction.

Popular Fallacies Concerning Hemorrhoids

J. F. MONTAGUE, M.D., F.A.C.S.

New York

During the course of a practice devoted entirely to rectocolonic diseases, I have frequently encountered certain fallacious opinions concerning the nature and characteristics of hemorrhoids and other fallacies concerning the methods now in vogue for their treatment. They are stated here as fallacies in the hope that others may not be led in error by them. Thus it is my opinion that it is erroneous to believe:

1. That extensive stretching of the sphincter muscles is a necessary preliminary to a hemorrhoid operation. The ordinary manipulation incident to grasping the hemorrhoids and bringing them down through the anal orifice is quite sufficient to induce dilatation of the sphincters to the extent compatible with their welfare. When deliberate dilatation is performed, particularly if done with instruments, the stretching of these muscles often resolves itself into a tearing of the sphincteric fibres.

2. That opium suppositories have any value in the palliation of the pain and soreness associated with hemorrhoids. Attempts to introduce the suppositories may readily traumatize the hemorrhoids far more than the opium could possibly sooth them; moreover, opium has no local anesthetic action whatsoever. Whatever opium is absorbed is certain to induce a constipation which in itself aggravates the hemorrhoidal condition.

3. That bleeding from hemorrhoids is beneficial. This opinion is frequently expressed by the laity, occasionally by physicians. In persons afflicted with high blood pressure, it is conceivable that the loss of blood may have a slight temporary effect upon the blood pressure but neither in this nor in any other circumstance can the bleeding be construed as being beneficial.

4. That the injection method of treating simple internal hemorrhoids is unethical. That method cannot be termed unethical because of the standing of some of those who use it. There are more ethical than unethical physicians using this method but because of its early association with irregulars, the charge that it is unethical is frequently made. It would be just as illogical to assert that local anesthesia is unethical because that, too, is used by the irregular practitioner.

5. That the injection method of treating hemorrhoids is applicable to all forms of hemorrhoids. Experience has shown that this method is only applicable to one type of hemorrhoid and that is to simple, uncomplicated internal hemorrhoids.

6. That hemorrhoids are neoplasms. This statement is frequently found in textbooks on rectal diseases. It is absolutely erroneous and is merely in keeping with the general lack of exact knowledge of pathological conditions on the subject of rectal diseases. The process of hemorrhoid formation is a degenerative lesion of the veins and is not a neoplasm.

7. That hemorrhoids are peculiar pathological conditions similar to no other condition of disease. The process of hemorrhoid formation is that of varicosity and is absolutely identical in principle with that of varicocele formation and varicose veins of the leg.

8. That the average set of statistics concerning the frequency of hemorrhoids in relation to sex, age and occupation are worth anything. The usual statistics are obtained under such special circumstances and with such variable factors that they are scarcely of any value. Thus, a gynecologist thinks hemorrhoids are more frequent in females; the general surgeon thinks that they are more frequent in males; an industrial surgeon believes they are more prevalent among the working classes; a general practitioner that they are found in all classes. It is a matter of circumstances altering cases.

9. That hemorrhoids are harmless conditions and of no clinical importance. The readiness with which suppositories and salves are recommended and used in this condition unfortunately support this view.

10. That it is not necessary to examine a patient who says he has "piles." There have been many cases of cancer of the rectum treated with suppositories because of this fallacy.

11. That hemorrhoids are due to the upright position of man. If this were true, the entire population of the earth would be entitled to hemorrhoids.

12. That it is necessary to place a rectal plug in the rectum after operation to prevent hemorrhage.

Carefulness in technic is the surest preventive of hemorrhage. When one uses the plug, retention of urine and pain are bound to follow.

13. That there is but one method of treating hemorrhoids. The exercise of judgment is far more beneficial to one's patients than consistency in riding a hobby.

14. That the selection of the type of treatment is entirely in the hands of the surgeon and that the patient has no right in the matter.

When the doctor himself becomes a patient, he is more than ready to give suggestions as to the type of treatment to be used on himself. He is just as adverse to an operation as the lay patient is.

15. That all rectal pains are due to piles. Take nothing for granted; take two minutes and give the patient the benefit of a rectoscopic examination.

Certain Experiences with Gallbladder Surgery*

GEORGE P. MULLER, M.D.
Philadelphia

The literature upon gallbladder disease and gallstones is of huge proportions and this communication may have little to merit its publication. But we often note that conclusions and figures of a decade or more ago are used to support opinions of the present day and do not represent current surgical practice. This paper is based on an experience comprising 128 operations for chronic gallbladder and tract diseases, including gallstones, done in the Hospital of the University of Pennsylvania and the Misericordia Hospital from September 1, 1922, to May 1, 1925.

Next to appendicitis, disease of the extrahepatic ducts and gallbladder is the most frequent of the lesions treated by the surgeon. Because of the relation to the liver and pancreas, they are much more interesting and very much more complicated than acute or chronic disease of the appendix. The great increase of interest in the function of the liver and of the gallbladder and the minute studies of the pathology of the gallbladder and the chemistry of the bile have been watched with great interest by surgeons, ever ready to apply the work of the laboratory to the solution of clinical problems.

The diagnosis of gallbladder disease is not particularly difficult if we keep certain facts in mind. Most cases occur in stout women who have borne children. In the series reported in this paper 82.5 per cent. were women. I have noted that most of these women have put on weight rather rapidly, and in many the early symptoms have developed shortly after the birth of a child. The ages varied from nineteen to seventy-six years and average forty-three years; fifty-nine per cent. of the patients were over forty and twelve per cent. were over sixty. This means the age when the patients came to operation and not the age at the onset of symptoms, which I have not calculated. It is interesting to recall that Alvarez (1) believes that on the average nearly twenty years elapses between onset and operation, a period characterized by many courses of treatment, most of them directed against such vague disorders as nervous indigestion, flatulent dyspepsia, intestinal autointoxication and the like. The attacks are usually sudden in onset and short in duration and are not amenable to dietary regulation.

Many patients complain of mild symptoms, suggesting a focal infection, such as chilliness, vague pains, joint pains, etc. During the attack the liver edge is nearly always tender. Sometimes later the attacks become more severe and often typical of acute cholecystitis. Colic occurs and the tender, distended gallbladder can be palpated. Usually these attacks extend over many years and are rarely severe enough to require an anodyne. Flatulence, epigastric distress, eructations and slight nausea may accompany the taking of food.

If we will remember that, next to appendicitis, gallbladder disease is the most frequent surgical lesion in the abdomen, that it is not necessary to wait for typical violent colic and never for jaundice, we will save lives and much postoperative suffering. In the series herein reported every chronic uncomplicated case recovered. Empyema, common duct stone, biliary cirrhosis and pancreatitis are the major complications. Extensive adhesions from frequent acute attacks prevent the complete recovery of the patient after cholecystectomy.

In recent years we have learned to lean heavily on the laboratory for assistance in diagnosis. A simple gastric analysis is not of much value, but it is well to know that the values are low in gallbladder dyspepsia, whereas in duodenal ulcer they are almost invariably high. Gatewood (2) found achlorhydria or hypoacidity in forty-five per cent. of a series of 192 patients with gallstone disease.

The x ray often helps materially in the diagnosis of pericholecystic adhesions. Spiderleg distortion may be seen, but is also present in the congenital membrane case; high fixation of the duodenum, fixation of the hepatic flexure, distortion of the pylorus to the right are all significant. The direct evidence is not so important unless positive. Thirty-one of my patients were x rayed for stones: In nine cases stones were diagnosed and in eight the finding was correct (eighty-nine per cent.); in nineteen cases the x ray evidence was negative, but in only five were gallstones absent and the x ray correct (twenty-six per cent.). In the other three the finding was simply a "visible gallbladder"; two had stones and one did not. Recently we have had added to our

*Read before a meeting of the College of Physicians, Philadelphia, November 4, 1925. From Surgical Division B, Hospital of the University of Pennsylvania.

resources the Graham test (cholecystography). It is not necessary to discuss this test as the literature now teems with papers and I had no experience with it in the group of cases under discussion. Only lately have we begun the routine use of the oral administration of the sodium tetraiodophenolphthalein. Moore (3) has reported a correct diagnosis of gallbladder pathology by cholecystography in 92.5 per cent. of fifty-five cases in which the diagnoses were confirmed by operation.

The exact function of the gallbladder is still hidden from us. Is it a vestigial organ, a diverticulum, of the primitive biliary tract? Does it serve for purposes of storage? Since McMaster has shown that the gallbladder of the dog can concentrate bile to about one tenth of its original bulk this explanation becomes more tenable. I can remember the time when the surgeon would point out the black viscid bile as pathological, when he found no gallstones at operation. Lyon uses this fact to demonstrate his B bile. We never see this concentrated bile in the gallbladder with markedly diseased walls. This concentration may be termed a sort of physiological stasis during periods of rest in digestion. Pathological conditions may occur when the cholesterol of the bile crystallizes into the clear single gallstone occasionally encountered. But suppose that pathological stasis occurs, from various causes, bacterial action may produce a catarrhal cholecystitis or a mural cholecystitis, and with precipitation of the bile pigment the multiple calcium pigment stones appear.

In 1905 I suggested (4) that an occasional cause of gallbladder infection might be the passage of microorganisms from the liver to the gallbladder through the superficial collecting lymphatics. Graham believes this is the frequent route and regards hepatitis as concomitant with cholecystitis. Heyd has worked on similar lines. So we are gradually coming to regard gallbladder infections as part of infection of the whole biliary system. The clinical studies from Lyon's laboratory point to the fact that he regards the gallbladder as of lesser importance, except in so far as surgery must remove it, in his method for artificial drainage of socalled poisoned bile.

Thus the liver is brought into prominence and a great deal of effort has been made to devise a method whereby liver function can be measured. So far these efforts have been balked by the apparent fact, as shown by Mann, that a considerable amount of the liver can be removed and the animal live and its liver function. The test devised by Rosenthal is that most commonly used. Further studies of the liver function lead us to suspect that the bile pigments are not formed in the true liver system. McNee follows Aschoff in believing that cells of the reticuloendothelial system elaborate the bile pigment. Then cells occur in the liver, spleen, bloodvessels and in other parts of the body, the larger portion being found in the walls of the blood sinuses of the liver and known as Kupffer cells. The polygonal cells of the liver probably play no part in this synthesis. The bilirubin may simply pass through them, to be excreted in the bile, or it may be chemically altered during the secretory process.

This work has led to the development of the van den Bergh, Fouchet, icterus index, and other tests which are believed to determine whether a jaundice is obstructive or hemolytic in origin. Dr. I. S. Ravdin, Dr. E. G. Ravdin, and myself (6) have described our experience with the van den Bergh test, but the work was only begun near the end of the series of operations here reported. We now find the test of extreme value, not as a test of liver function, but as a test of the working of the extrahepatic passages.

The taking of a minute case history is invaluable in the study of a supposed gallbladder infection, or a case of gallstones, but it most certainly must be associated with accurate modern laboratory tests if we hope to make a high percentage of accurate predictions as to the pathological condition present and the possibility of successful surgical treatment. The discussion in this paper is based on the results of 128 operations on 126 patients. There were eight deaths, a mortality of six and three tenths per cent. The cases are consecutive and comprise all of the operations done by myself and my assistants except those operations on the gallbladder performed in the course of the surgical treatment of acute pancreatitis, malignant disease of the pancreas, splenomegaly and one case of reconstruction of the common duct. For purposes of analysis the series is divided into:

	Cases	*Deaths*
Acute suppurative cholecystitis	19	1
Acute cholecystitis with common duct obstruction	5	2
Chronic cholecystitis	78	0
Chronic common duct obstruction	26	5

This grouping is found convenient because the principal problems in treatment concern the management of the acute empyema, or gangrene of the gallbladder, where the question of primary cholecystostomy or cholecystectomy must be settled; the association of a common duct stone with acute suppuration of the gallbladder and possibly of the main ducts; and the management of the ordinary common duct stone, especially with marked jaundice, hepatitis and pancreatitis. The ordinary chronic cholecystitis, with or without stones, is a comparatively simple problem.

1. *Acute suppurative cholecystitis.*—This group (nineteen cases) were characterized by clinical evidences of acute inflammation, such as tenderness, rigidity, fever and leucocytosis, and the pathologic appearance of acute suppuration. Sometimes the gallbladder was moderately diseased, but more often it was greatly swollen, intensely congested and with walls often nearly a centimetre in thickness. The evidence of edema was conspicuous. The liver in the vicinity of the gallbladder usually showed the appearance of congestion. In fifteen cases the gallbladder contained multiple stones, in three a single stone and in one there were no stones. Cholecystostomy was performed five times with no deaths; two of the patients required a cholecystectomy later. Cholecystectomy was done on fourteen patients with one death. The notes in this case were:

Case I.—Mrs. McG. (No. 454), aged fifty-four years, extremely stout. Four attacks of biliary colic, starting one year ago. Had typhoid fever at age

fourteen; acute appendicitis with operation eleven years previously. Admitted, University Hospital, November 20, 1922, suffering from pain, fever, a leucocytosis of 25,400 and a distended gallbladder. She was slightly jaundiced. The lungs were clear and the heart sounds regular and of good quality. The diagnosis of empyema of the gallbladder was made.

Operation was performed the next day under gas ether anesthesia and lasted forty minutes. Transverse incision. A large, acutely inflamed gallbladder containing pus and many stones was found. Cholecystectomy was done and three drains introduced. There were no anesthetic complications. I saw her at about 10 p. m., and was rather pleased with her condition, although she was restless and a little irritated because we could not get her off to sleep. Her temperature was about 102° and the pulse 128. She was given a small dose, 1-200 gr., of scopolamine because I did not want her given any more morphine. At about the same time she voided five ounces of urine and was not at any time uremic. At 12 o'clock the temperature was 102° and the pulse 120; at 2:30 p. m. the temperature and pulse were practically unchanged. At 3 a. m. the nurse noted that the patient's circulation suddenly had failed; a few minutes later she was given intravenous saline solution and other stimulation, but failed to respond and died at four o'clock, eighteen hours after operation. As no autopsy was allowed, we can merely speculate upon the cause of death. Acute dilatation of a fatty heart weakened by disease, sepsis and the shock of operation, are the most probable causes.

Three points for discussion are suggested. Should immediate operation be performed in these cases, or is it justifiable to wait a few days in the hope that eliminative measures and the use of digitalis will improve the condition of the patient? I think that no hard and fast rule can be followed. While there is not the same urgency as in acute appendicitis, nothing particular is gained by a long delay. I usually wait for twenty-four to forty-eight hours only. The fact that there was only one death in nineteen cases (five and three tenths per cent.) shows that we got along fairly well. Perhaps it would have been better to have employed local anesthesia, but I am partial to cholecystectomy and find local anesthesia most difficult in stout people when removal of the gallbladder is contemplated. Nitrous oxide or ethylene rarely suffices and some ether is usually necessary. On the other hand, cholecystostomy can be done readily under local anesthesia and perhaps should be considered the operation of choice in this group, particularly if the surgeon has not had much experience. A large percentage will require a second operation later, but the ultimate mortality is the important thing to hold in mind. Cholecystectomy is easy to do, except in those cases which have perforated and are surrounded by a local abscess. Troublesome oozing from the inflamed liver bed is the principal complication and as packing is fraught with later danger I think that on the whole cholecystostomy is safer.

2. *Acute cholecystitis with common duct obstruction.*—This group, fortunately small in number, gave me a mortality of forty per cent. in five cases. In two cases the gallbladder contained multiple stones, in one a single stone and in two there were no stones. In all five a cholecystectomy was performed. In the three patients who recovered, the obstruction was caused by stone in two cases and pancreatitis in the other. In one the common duct and the gallbladder contained socalled white bile. One patient was reoperated upon two months later for fistula, which was then closed.

One of the fatalities was a pure error in technic. The patient had a cholecystostomy nine years previously and was admitted acutely ill with empyema of the gallbladder and jaundice. Adhesions were extremely dense and I so cut and injured the colon that a resection was necessary. She died two days later from peritonitis. The other death occurred from cholangitis and hepatic depression. The notes are as follows:

Case II.—Mrs. M. F. (No. 4945), aged sixty-four years. Very aged, indigestion for five years. Twenty years ago had single attack of pain associated with jaundice; always sallow; three days before admission had acute attack. Admitted with symptoms of acute empyema of the gallbladder. Leucocytosis of 20,000. Plasma carbon dioxide, forty-eight volumes per cent. Patient was treated for a period of four days with continuous hypodermoclysis, digitalis, etc.

Operation on January 31st, under local anesthesia. Gallbladder was found filled with stones and was removed. No exploration was done of the common duct, but a tube was pushed through the cystic duct and established drainage. The liver was extensively involved, with biliary cirrhosis. The patient became drowsy and the blood urea showed seventy-two mgms. per hundred c.c. On February 6th it was thought that she was on the road to recovery, but two days later the temperature and pulse began to rise. In spite of all treatment death occurred fifteen days after operation. No autopsy was obtained.

I will not comment at length upon this group, the gallbladder problem is similar to that in the first group and the common duct problem to that in the fourth group. Here we have both combined and the patient must react against the sepsis and the obstruction to the bile flow. Note that in the second fatality the common duct drainage was attained by the simplest method possible, namely, the utilization of the stump of the cystic duct. Cholecystostomy alone is useless, as a rule, because several days will elapse before bile will flow through the cystic duct, obstructed as it is by the inflammatory swelling. The common duct must be tapped, although the stone should not be sought by spooning. It can be removed if immediately accessible. Even with the best technic the outlook in these cases is always serious.

3. *Chronic cholecystitis.*—This constitutes the largest group and includes twenty-four cases of simple cholecystitis and fifty-four cases of calculous cholecystitis (nine single stones and forty-five multiple stones). Cholecystectomy was performed seventy-three times and cholecystostomy five times. There were no deaths in either series. In thirty-six cases the cholecystectomy was the only operation performed; additional procedures were done on thirty-eight patients, removal of the appendix (thirty

times), gastrojejunostomy (five times), miscellaneous gynecological procedures (five times). Rammstedt pyloroplasty, appendix stump, adhesions and excision tuberculous mesenteric glands, one each. Twice a cholecystostomy was followed by cholecystectomy.

Cholecystectomy for noncalculous disease was considered indicated when the gallbladder was evidently diseased by reason of thickening, pericholecystic adhesions or the aspiration of bile mud. In one case a cholecystostomy was done. The patient was jaundiced and the preoperative diagnosis was carcinoma of the pancreas. Nothing except extensive adhesions was found as a cause of the jaundice. Cholecystostomy was thought to be the safest treatment and two and a half years later the patient reports that he is perfectly well. The fistula closed in one month.

Cholecystectomy has been the operation of choice in calculous disease of the gallbladder and I cannot be convinced that simple drainage offers permanent cure in any degree comparable to removal. The literature is filled with evidence that bears this out and need not be quoted here. Naturally there may be cases where the presence of pancreatitis may seem to justify bile drainage, but if the gallbladder is in good condition internal drainage (cholecystgastrostomy, etc.) is better than external and if the gallbladder is extensively diseased it is probable that the cystic duct is occluded. The fact that there were no deaths after cholecystectomy in this group shows that the operation is safe enough. The end results will be considered later. Two patients had had a previous cholecystostomy elsewhere and had a recurrence of gallstones.

Five patients had coincident gallbladder disease and duodenal ulcer. In four the gallbladder contained multiple stones, in one there were no stones, but the gallbladder was thickened and adherent and considered primarily involved. In all a posterior gastrojejunostomy and a cholecystectomy was performed. In three the appendix was also removed. In one patient I performed a Rammstedt operation because the pylorus seemed small and stenotic. As noted the appendix was removed many times, sometimes through the upper transverse incision almost always used, and sometimes through a separate McBurney incision. The association of appendicitis and gallbladder disease has been much discussed, and without proper investigation I am yet inclined to think that in the absence of an acute attack the etiological factor of the appendix is usually exaggerated. The percentage of crooked, adherent appendices will be found just as great when operating for fibroids of the uterus as for gallstones.

4. *Chronic cholecystitis and common duct obstruction.*—This group comprised twenty-six cases with five deaths (19.2 per cent.). Thirteen patients had multiple stones in the gallbladder and stones in the common duct. Cholecystectomy was done, the stones removed from the common duct and the duct drained with a T tube; three of these died. In three cases the gallbladder was removed for multiple stones and the common duct found to contain white bile. The duct was drained, the obstructing stone not being seen or felt. Pancreatitis was present and might have been the cause of the obstruction; two of these patients died but the third, a woman aged seventy-six years, deeply jaundiced, recovered and is well seven months after operation. Four patients had stones in the gallbladder but none in the duct. They recovered after cholecystectomy and duct drainage. Three patients had duct stones but no gallbladder stones and two had no stones; all recovered after cholecystectomy and duct drainage. One patient had a cholecystectomy three years previously and was found to have duct stones. She recovered.

It is evident that, from the viewpoint of mortality, this group is the most important one, and while we may be caustic in our criticism of patient or physician for delay yet the fact remains that the surgeon must rescue the patient. There is not space to discuss many of the points involved. The patient must be prepared by the method best brought out by Walters, of the Mayo Clinic. Haste is rarely indicated and three or four days of preoperative preparation are absolutely necessary. Water, glucose, calcium chloride and perhaps digitalis are the main things. From some recent experience I am inclined to think that a well executed nonsurgical drainage carried on for a few days is helpful. Sweet thinks that ether is a liver poison only second to chloroform, hence ethylene or nitrous oxide reinforced by novocaine locally is the anesthetic of choice. Sometimes local anesthesia alone suffices, but I have not been able to manage choledochostomy and cholecystectomy by local anesthetics.

Cholecystostomy is easily done under local anesthesia, and in the very ill patient, with a high van den Bergh test (ten to twelve units, for example) without tight jaundice, with some fever, some mental depression, or with a high degree of blood sugar, close attention should be paid to the gallbladder to see if the cystic duct is patulous or not. If so, a primary cholecystostomy is the operation of choice. Those who are very obese are severely jaundiced, have a high blood pressure and interstitial nephritis, are also grave risks. If the gallbladder is not capable of draining bile, the common duct must be opened and the liver drained; but, except in those only moderately ill, spooning of the liver ducts and retroduodenal pressure or trauma must absolutely be avoided. It is true that many patients, quite sick, recover after a complete operation, but the group mortality is too high and the two stage procedure must be extended if we want hope of having less deaths. The following is an example of the sequence of events in a fatal case.

Case III.—No. 3345. Mrs. A. P., aged fifty-one years, emaciated. Symptoms began acutely seven months previously, followed by numerous attacks. Admitted intensely jaundiced and suffering pain. Says she has lost 120 pounds in weight in the last six months. Blood pressure was 140 systolic and 90 diastolic. She was treated in the medical wards for a week and then transferred for operation.

Operation April 22, 1924. Novocaine local and gas anesthesia. Duration one hour. The gallbladder contained two stones impacted in the cystic duct and was removed. The common duct was opened and contained a lot of soft pigment. The common duct was evidently compressed by the stones in the cystic duct. When the T tube was introduced, bile began to flow freely. The liver looked markedly

cirrhotic. Following operation the patient steadily declined, although draining large quantities of bile. Blood transfusion was done, but the patient soon developed the low blood pressure and the weak though not rapid pulse that we have associated with pancreatic asthenia. Death occurred ten days after operation. Autopsy showed no obstruction of common duct and the pancreas appeared grossly normal.

The other deaths in this group occurred, nine, twelve, sixteen and seventeen days after operation, giving an average of 12.8 days for the five. Apparently death occurred from what has been termed cholemia, or, as Heyd expresses it, from liver exhaustion. None of the patients died early from vasomotor depression, but I have seen this type of death several times. I can remember one death in the third group described by Heyd in which coma occurs almost immediately after operation and early death results. He says it has occurred after rather simple types of operation on the biliary apparatus, and, with Killian, he has found such patients show a very high carbon dioxide combining power representing as much as 80 to 100 volumes per cent.

Jaundice is a symptom and indicative of obstruction, but takes on supreme importance because nearly all of the fatalities occur in the group in which it is manifest. In my series seven of the eight patients who died were jaundiced. In the group operated on in the University Hospital, thirty-one (forty per cent.) stated that jaundice has been present during one or more of the attacks. In eleven the gallbladder only contained stones and one case was noncalculous. In three patients stones were present in the common duct, but there was no jaundice. This finding is important because it represents six and five tenths per cent. of the group and shows the supreme importance of palpating the common duct in all cases.

There is another feature of importance, that is, the failure to detect stones even by palpation. Kehr (6) found that forty-six per cent. of thirty-six cases in which palpation of the common duct was negative had calculi in either the hepatic ducts or retroduodenal part of the common duct, and Eisendrath (7) in a series of thirty-four cases in which palpation was negative, found after choledochotomy that he was wrong in 32.3 per cent. of times. Perhaps the old rule of Kehr is a good one—the common duct should be opened when the duct is dilated and thick walled, when there is pancreatitis, and when the gallbladder or cystic duct contained numerous small stones. In the eleven cases of this series in which a history of jaundice was elicited, the trouble confined to the gallbladder and only a cholecystectomy done, every patient has been traced and with one exception is perfectly well; he complains of some gas after meals. This series should be watched over a period of years.

Recurrence.—Ten patients in this series had multiple operations on the biliary tract; four had had a previous cholecystostomy done elsewhere and required a cholecystectomy; in two cases we did a cholecystostomy and later removed the gallbladder; one patient was reoperated upon by Dr. Godfrey for stricture of the common duct due to adhesions, one for a common duct fistula and one for a cystic duct leak with bile cyst, one patient had had a cholecystectomy done by me in another hospital three years previously and returned with a duct stone. None of the patients in this series has so far suffered from recurrent symptoms due to duct stone.

End results.—An effort was made to trace the end results in these cases and either personally or by letter the condition of the patient ascertained from six months to two and a half years after operation.

	Cases Traced	*Well*	*Improved*	*Unimproved*	*Not Traced*
1. Acute cholecystitis					
Cholecystectomy ..	13	12	1	0	0
Cholecystostomy ..	4	3	1	0	1
II. Acute cholecystitis and duct stone	3	3	0	0	0
III. Chronic cholecystitis					
Without stone	23	16	6	1	1
With stone	45	38	5	2	7
IV. Common duct stone..	18	13	3	2	3
	106	85	16	5	12

As the table indicates, eighty-five of the traced patients or eighty per cent., are entirely cured of all previous symptoms for which the operation was performed. The statement of the patient is the standard. In the "improved" group (15.2 per cent.) are included those patients who still complain of some belching after eating or adhesion pain. Two patients were reoperated on, one for adhesions and one for a bile cyst but are now well; they are classed in the improved group. No patient has reported symptoms suggestive of further stone trouble. It is interesting to note that 84.4 per cent. of Group III. with gallstones claim to be perfectly well whereas only seventy per cent. of the simple cholecystitis group are without symptoms. Apparently there was an element of error in the selection of cholecystectomy for some of these patients. We expected that the acute group would suffer symptoms by reason of the greater drainage with consequent adhesion formation but on the contrary ninety per cent. of these patients state they are in perfect health.

The common duct stone groups of cases show an end result of 76.2 per cent. of cure. Three patients died after leaving the hospital, one from chronic pancreatitis, one from intestinal obstruction in the lower abdomen, and one after an operation for adhesions. This patient had had a cholecystostomy elsewhere, came to me for persistent trouble and I removed the gallbladder. Later, her symptoms returned and she again returned but died after the third operation. One of the unimproved cases had had a previous cholecystostomy and there were many adhesions. It would seem as though a final good result in about ninety-five per cent. of the cases speaks well for surgical treatment.

In considering end results we must remember that after other treatment than surgery, such as diet, medicine and duodenal drainage, remissions frequently occur and irreparable liver damage may occur before operation is advised. The patient may recover but the infection in the gallbladder persists and acts as a focus of infection for other organs.

McMaster (8) experimentally has shown that the output and concentration of cholesterol in the bile are subject to profound modification by dietary influence. When a ration rich in cholesterol is given, the amount of substance in the bile greatly increases. This work has led us to give our patients a diet sheet similar to the one advised by Moynihan (9). The relation of diet to postoperative symptoms is also well discussed by Wilensky (10), who emphasizes the importance of a diet free from fats and lipoid bodies.

Gastrojejunostomy and Gastric Carcinoma

HARRY C. REYNOLDS, M.D., F.A.C.S.
and SIGURD W. JOHNSEN, M.D.
Passaic, N. J.

On November 24, 1925, a patient was admitted to the hospital, complaining of epigastric pain and distress of eight months' duration. On x ray examination a diagnosis of pathological gastrojejunostomy and possible gastric carcinoma, was made. Exploratory laparotomy confirmed this diagnosis. He had been perfectly well up to eight months ago, had had no operations and no serious illnesses, thereby justifying our reporting the case as of unusual interest.

Case.—K. T., male, forty-eight years of age, born in Russian Poland, emigrating to the United States in 1913. His family was still in Poland. He spoke very little English. He was a laborer, in the building trade, married twenty-four years, and had two children, aged fourteen and nineteen years respectively. His family history was negative; no cancer, tuberculosis, or cardiac disease. His complaint was pain in the epigastrium for past eight months.

Eight months ago the patient first noticed pain in the epigastrium which radiated to the right costal margin. He had no vomiting or belching, but began to lose weight and strength. He had had to stop work four months ago. He did not recall having had any childhood diseases. His health had always been good until eight months ago. There was no history of acute infectious diseases, nor operations. His appetite had always been good before the onset of present illness. His bowels had been open and regular, no constipation or diarrhea. He was a heavy drinker of alcohol, a heavy smoker, and had irregular habits of eating, sleeping and drinking. His best weight was 137 pounds; present weight ninety-eight pounds.

He was a middleaged man of medium build, moderately emaciated, and appeared chronically ill. The pupils were equal and regular, and reacted to light and accommodation. His teeth were in poor condition, many being carious; the pharynx was normal. The neck showed no abnormalities. His chest was emaciated, veins prominent, moderate myxedema. Percussion note was resonant, breath sounds were vesicular throughout; no râles.

Examination of the heart showed normal percussion dullness borders. Apex beat was not seen, and felt as a diffuse, weak impulse in fifth interspace, midclavicular line. Pulse rate was slow, regular, no murmurs. Sounds at apex were of fair quality; at base P2=A2. The abdomen was flat and emaciated. There was a slight amount of tenderness in the epigastrium; no masses felt. Liver and spleen were not palpable. Slight tenderness was noted along the right costal margin on deep palpation.

The extremities showed no abnormalities. Knee jerks were present and active.

A provisional diagnosis of carcinoma of the stomach was made.

Laboratory findings.—Gastric analysis showed a small amount of mucus obtained one hour after an Ewald meal by a Rehfuss tube; not suitable for analysis. Urine, specific gravity, 1,024; no albumin or sugar. Blood: hemoglobin, 90 per cent.; red cells, 4,800,000; leucocytes, 7,400; polymorphonuclears, 64 per cent.; small lymphocytes, 22 per cent.; large lymphocytes, 6 per cent.; eosinophiles, 2 per cent.; basophiles, 2 per cent.; myelocytes, 4 per cent. Wassermann was negative.

X ray report.—Sthenic habitus. Position was slightly hypersthenic. Axis was transverse. Mobility was somewhat restricted. Tone and peristalsis could not be accurately determined. Lowest point of greater curvature was two and one half inches above the interspinous line. On fluoroscopic examination a pathological opening between the greater curvature of the stomach and the jejunum (?) was plainly visible. The meal escaped so rapidly that a complete stomach outline could not be obtained. There was a marked filling defect along the major portion of the greater curvature. The meal was also seen to escape through the pylorus. The duodenal cap filled completely.

Six hour examination: The head of the meal was just beyond the hepatic flexure, the tail in the terminal ileum. There was no gastric residue. Twenty-four hour examination: The head of the meal was in the rectum, the tail in the cecum. The appendix was not visualized. Colon enema observed under fluoroscope showed that the enema filled rectum, sigmoid, descending colon and transverse colon as far as the hepatic flexure without defect. At this point there was some hesitation, but the meal apparently reached the cecum.

*From the Passaic General Hospital.

Abnormal findings.—Defective filling of the stomach on the greater curvature and a pathological opening to the jejunum.

Operative findings.—Exploratory laparotomy was performed on December 2, 1925. A right rectus incision five inches long was made. The greater omentum was found decreased in size and slightly thickened; no masses.

The stomach was decreased in size, semitransverse position, pylorus free and mobile, but retracted towards left. Entire stomach was markedly thickened and firm extending uniformly from pylorus to cardia. Diffuse scirrhous carcinoma diagnosed.

On the posterior surface near the cardia, on its greater curvature, there was a small area adherent to a loop of the jejunum below Treitz's ligament about two centimetres in diameter; around the periphery, a few bands of adhesions were seen; no adhesions to omentum or peritoneum.

The condition was diagnosed as pathological gastrojejunostomy.

The liver was normal in size, shape and consistency. No nodules were noted. The mesenteric lymph nodes showed no generalized enlarged masses, no metastatic growths apparent. The spleen was normal in size and consistency.

Acute Postoperative Dilatation of the Stomach*

ARTHUR J. PARKER, M.D.

Brooklyn, N. Y.

Acute postoperative dilatation of the stomach was first recognized by Riedel in 1892. Since then it has become quite widely known as an important and dangerous complication of any surgical procedure. Even at the present time, however, there are many cases which suffer a stormy postoperative convalescence or go on to a fatal termination because this condition is not promptly diagnosed and properly treated.

Acute dilatation of the stomach may occur in any person regardless of age, sex, the operation performed or the anesthetic employed whether general or local. Gastroptosis, enteroptosis and digestive disturbances are predisposing causes. A history or previous postoperative dilatation is a danger signal not to be ignored because it is very prone to recur.

There are two main theories advanced in explanation of this postoperative phenomenon. The first and perhaps the most generally accepted is that of primary paralysis of the stomach due to some change in the nervous mechanism of the organ. This change is caused by direct trauma to the nerves or more likely by some toxic agent acting centrally. The injurious substance may be bacterial or chemical. The toxic idea is borne out by the occurrence of acute dilatation in toxic diseases such as pneumonia and eclampsia and by the presence of urinary suppression and mental disturbances suggesting toxemia in postoperative dilatation.

The second theory is that the duodenum is mechanically obstructed by pressure from the mesenteric artery as it passes behind the root of the mesentery. Isidore Cohn quoting Connor, who favors this theory, states that in only fifty-five per cent. of cases can obstruction at this point be demonstrated. Against this theory is the rapidity of onset of the dilatation, cases being reported where it has occurred within fifteen minutes during the course of an operation, and occasionally the dilatation has been found to extend below the duodenum. Dilatation also occurs after gastrojejunostomy. It is easy, however, to conceive of a stomach primarily dilated sagging downward, and thereby causing a point of constriction in the duodenum.

The symptoms may appear at any time during the operation or the postoperative convalescence. These are vomiting, rapid pulse, rapid and difficult respiration, epigastric distension, thirst, scanty urine and terminal collapse.

The vomiting alone is diagnostic, when typical, small amounts of a greenish or brownish fluid containing black flakes spill from the mouth frequently and without the slightest expulsive effort. If this type of vomiting occurs only once it is wise to institute treatment immediately, and not expectantly await a recurrence to confirm the diagnosis, because there are cases which go on to collapse and even death without the appearance of this symptom.

The collapse in dilatation is a rapidly approaching terminal state, following a train of nervous symptoms made evident by an apprehensive worried expression and restlessness increasing to delirium.

The pulse increases in rapidity and decreases in volume until it reaches a rate which cannot be counted or becomes imperceptible. It may or may not be irregular.

Thirst is marked and cannot be satisfied even though water is allowed. The giving of water only increases the amount of fluid in the dilated stomach and neither alleviates the thirst nor increases the urinary output, which is scanty and concentrated.

Respiration is rapid and difficult. Epigastric distension is more or less marked, but does not always indicate the degree of gastric dilatation. Tympany elicited over the epigastrium frequently extends high into the left side of the thorax.

Diagnosis is easily made upon the appearance of the characteristic black or brownish vomitus or upon the presence of tympanitic epigastric distention alone. If there is any suspicion that dilatation of the stomach exists, treatment for this condition may be immediately instituted with very little danger and with a great probability of marked relief.

Bloodgood considers high intestinal obstruction in which pain is more marked and distention less evi-

*From the Surgical Department New York Postgraduate Medical School and Hospital. Service of Dr. Charles Gordon Heyd.

dent as the most confusing factor in differential diagnosis.

The highest death rate reported by Conner in 1907 was 92.5 per cent. Since then earlier recognition and institution of proper treatment have greatly reduced the mortality of this complication, Borchgrevink reporting 26.2 per cent. in 1913. The gravity of the case is best judged by the rapidity and quality of the pulse.

The treatment is simple and may be divided into prophylactic, mechanical, chemical, and operative.

Prevention of the condition is attempted by instituting immediate postural treatment in all cases having a history of gastric distress and especially of a previous postoperative dilatation of the stomach. In upper abdominal operations careful handling of the viscera, speed and the semirecumbent position assumed as soon as the patient is out of the anesthetic, tend to reduce the occurrence of gastric dilatation.

Once diagnosed, the stomach is immediately lavaged, using tap water heated to a temperature between 110 and 120° F. until the return is clear. A saline or bicarbonate solution may be used instead of tap water with questionable advantage. Lavage should be repeated as frequently as necessary and over as long a period as the condition persists. In acute postoperative dilatation there is no contraindication to the use of the stomach tube. The patient is then placed in the prone position with the pelvis raised or if this is not possible in a right lateral position. The postural treatment alone has been productive of remarkable results.

In the chemical treatment, strychnine, pituitary gland preparations, atropine, morphine and apomorphine have been used with doubtful effect. Saline infusions are most certainly of value in replacing the enormous quantity of fluid lost and according to the animal experiments of Dragstedt, saline or Ringer's solution seems to be a neutralizing agent in the toxemia accompanying acute gastric dilatation. One patient not benefitted by posture and only temporarily by lavage over a period of seven weeks following cholecystectomy promptly recovered after direct transfusion of 500 c. c. of normal blood followed by one saline hypodermoclysis (personal experience).

CONCLUSIONS

1. Acute dilatation may complicate any operative case.
2. The surgeon should have this complication constantly in mind.
3. In case of doubt, it is more dangerous not to use the stomach tube than to use it.
4. Repeated gastric lavage, postural treatment and saline infusion are life saving measures.

A Case of Intestinal Hemorrhage in Pneumococcal Infection

With Clinical Remarks

JEAN CHATARD, M.D.
Bordeaux, France

Case.—C. J., aged forty-eight years, entered the service of Professor Arnozan June 1, 1922, with fever and pain in the right hypochondrium. A week previously the patient had expelled a tænia.

For the past week patient complained of twisting pain in the abdomen and epigastrium, occurring at irregular intervals during the day and lasting for about thirty minutes, accompanied by bilious dejections. Some attacks occurred in the night, but were much less severe; appetite poor; general lassitude.

Three days before entering the hospital the patient experienced severe pain in both lumbar regions radiating forwards towards the epigastrium, followed by nausea and cold sweats. Since this attack anorexia was complete, food vomited immediately, constant thirst, insomnia, nocturnal restlessness and slight headache. Vertigo when sitting up; no epistaxis, diarrhea or constipation. General depression.

Examination.—General prostration, somnolence; slight degree of icterus. Replies readily to questions. Temperature 100.5° F., pulse 92. Tongue dry, abdomen slightly tender all over, but more so over both hypochondria. Liver normal, spleen slightly enlarged. A few râles at both bases. Circulatory and nervous systems apparently normal. Urine, 500 c. c., dark color; no albumin or sugar. Hemoculture on bile negative. He had had typhoid at nine years, which was complicated, and influenza in 1918. Ethylism.

June 6th. Temperature 100.5° F. As it was 104° F. the day previously, this drop led one to suppose that an amelioration would take place, but a melena occurred on June 7th. On June 8th Meyer's reaction was markedly positive in the stools, but they did not contain any leucocytes. Blood count: polynuclears 67 per cent.; lymphocytes 22 per cent.; large mononuclears 5 per cent.; small mononuclears 5 per cent.; eosinophiles 1 per cent.

June 9th. Hemoculture negative. TAB serodiagnosis negative. Reaction=13.5—6.

June 12th. Hemoculture on broth negative.

June 14th. Severe enterorrhagia consisting of bright red blood. Morning temperature 102° F. Evening 100° F. Auscultation revealed signs of a pleural collection on right, but puncture gave issue to very little fluid. Rivalta positive. The fluid gave a positive macrophagic reaction, but was bacteria free. Trace of albumin in urine.

June 15th. Blood count: neutrophile polynuclears 83 per cent.; large mononuclears 2 per cent.; small mononuclears 9 per cent.; lymphocytes 6 per cent.

June 16th. Culture of bile obtained by duodenal tubage negative.

June 18th. Blood pressure 14—8=2 index.

June 19th. Examination of feces after homogeneization revealed no parasites; blood examination negative.

Urine=850 c. c., cloudy, rather abundant sediment, acid, sp. gr. at 15° C., 1,009; urea 11 gr. 20 P^2O^2 1 gr. 10, sodium chloride 1 gr. 80, albumin 0 gr. 06. A few leucocytes, numerous red cells. Pneumococci distinctly present.

June 30th. Bulging of right side of thorax. Dullness over the entire lung, vibrations abolished; complete respiratory silence, no souffle. Exploratory puncture in eighth intercostal space gave issue to bloody seropus. Another puncture in the sixth intercostal space withdrew a large amount of yellow pus containing a pure culture of pneumococci. Operation for empyema gave issue to about 300 c. c. of poorly mixed pus. Blood pressure before operation: 13—6=2.

July 1st. Blood pressure: 14—7=3. Subcutaneous injection of 100 c. c. antipneumococcal serum. During the day the patient vomitted well mixed greenish pus.

July 2nd. Fifty c. c. serum injected and 40 c. c. on July 4th, 6th and 8th. Blood pressure 18—7=2.

July 10th. Blood pressure 18—7.

July 18th. Injection 20 c. c. serum. Temperature varied between 99° and 100° F. Patient decidedly better.

July 26th. Urine=1500 c. c., cloudy, considerable sediment. Urea 8 gr. 5, phosphates 0 gr. 20, chlorides 4 gr. 50, albumin 0 gr. 30. A few leucocytes and red cells, some crystals of uric acid, no pneumococci.

August 9th. Radioscopic examination showed both apices dark, did not clear up by coughing; large opaque area under left clavicle; both bases opaque; diaphragm functionated well, sinus free. Left heart greatly dilated. Transversal dilatation of vessels.

August 30th. Patient discharged in convalescence. Diagnosis: pneumococcal infection—melena—enterorrhagia (pure red blood)—pneumococcal empyema —pneumococcal hematuric nephritis.

I have been able to collect only eight cases of intestinal hemorrhage in subjects with pneumococcal infection from the literature; there are probably others, but it is evident that this complication is infrequent. In 1905 Schneider published a paper on the intestinal complications of pneumonia and divides these into three forms, viz., the simple enteric, dysenteric and ulcerating hemorrhagic forms. The first two forms—the first being far more common than the second—need not detain us. As to the third it seems to me that although it occasionally corresponds with a pathological reality, it clinically is not sufficiently defined. In point of fact, an erosion must be distinguished from an ulceration and the hemorrhagic is not always due to ulceration.

It may be objected that every time there is ulceration of any section of the intestine that bleeding occurs and the examination of the feces for blood renders great service in the diagnosis of numerous digestive disorders. But these occult hemorrhages are not the same as true hemorrhage which in themselves constitute a complication. For this reason I would divide the third form into two types, namely, the ulcerating and the hemorrhagic.

The ulcerating type usually gives rise to no immediate clinical symptom, unless it be perforation of the gut. This type is often overlooked but we now know that many true gastric ulcers and erosions, likewise of the duodenum, are the result of a toxemia or septicemia occurring at some time in the life of the patient.

Now the toxin of the pneumococcus and pneumonia itself are no exceptions to this law as is made evident by Griffon and Bezançon's experiments, who experimentally produced ulcerations in the guineapig; then we have Griffon's clinical evidence which—contrary to usual events—corroborates in man the experimental results obtained in animals. Lastly we have numerous other instances where ulcers or erosions have been found in the intestine at autopsy of pneumonia cases although these lesions gave rise to no symptoms during life.

Laisné, Billard, Chambers, Claus, Colombo, Simmonds, Krannhals, Hagenbach, Lemierre and Lévesque—not to mention others—have published similar cases in which ulcers due to the pneumococcus or its toxins remained clinically silent, excepting in Claus and Hagenbach's patient in whom symptoms of perforation occurred, as well as in Lemierre's case, in which the disease was early complicated by anuria and collapsus followed by death. The ulcers were found at autopsy.

The hemorrhagic type may simply be a complication of the preceding type or, on the contrary, it may be completely autonomous. The blood voided is fresh —bright red—or transformed during its retention in the gut, and in itself is an evident clinical symptom. Occult hemorrhage should, on the contrary, is due to the simple ulcerating type of the process and may be utilized for diagnostic purposes during the evolution of pneumococcal infections. I would add that occult intestinal hemorrhage should be systematically searched for and when detected may be the means of directing a treatment for avoiding perforation of the gut, a possibility to be feared in these circumstances.

Claus's case, in which perforation of the lesser curvature of the stomach and descending colon, followed by peritonitis, occurring ten days after the beginning of convalescence from pneumonia, clearly leads to the conclusion that a strict diet and absolute rest in bed might prevent this lethal complication.

The cases I have been able to collect show that intestinal hemorrhage is more prone to arise in pneumonia, since in eight out of nine instances of pneumococcal infection this was the case, and the case here reported is the only one that I know of in which the process was a pneumococcia without any localization—at least at the onset. Intestinal hemorrhage is more prone to ensue in serious cases of pneumonia or when this lung process develops in debilitated or alcoholic subjects. However, Vialard's patient was a young girl of seventeen, with a mild pneumonia, while at the other extreme Mathieu's patient presented a pneumonia of particularly alarming type. The seventeen year old girl referred to was the youngest case in which intestinal hemorrhage occurred, while in the other cases the patients ranged from thirty-two to fifty-one years of age.

The date of the appearance of the hematemesis or enterorrhagias in pneumococcal processes varies between the fifth to the twelfth day and I am aware of no case in which it occurred before the fifth day. In two instances it took place on the sixth, and in two others on the twelfth day. Vialard's patient is the only one of which I have notes whose hemorrhage arose as late as the twenty-seventh day.

In the case here reported it is rather difficult to fix the exact onset of the affection as there were no classic symptoms of the onset of the pneumonia. However, bright red blood was passed on the twelfth day in hospital and eight days previously the patient had melena.

PREMONITORY SYMPTOMS

I have endeavored to ascertain—but unsuccessfully—if there exist any absolutely evident and constant premonitory symptoms of these intestinal hemorrhages. However, in Vialard's two cases the temperature dropped the day before the loss of blood took place. In his first case the temperature went down to 97.5° F. and then rose slightly, and the evening before the hemorrhage the patient had a syncope followed by great general prostration. In his second case, two nights before the loss of blood there was a slight rise of temperature accompanied by a feeling of well being which might have been a sign of approaching convalescence, but the evening before the enterorrhagia there was a sudden change, namely, general prostration, pallor, with dimness of sight and hearing, all these symptoms being accompanied by a sudden drop in the temperature. On the following day there was an enterorrhagia to the amount of 500 c. c.

In Dieulafoy's case the day before the occurrence of the hematemesis, the patient had a bad night with insomnia, restlessness, gastric pain and nausea, but the temperature showed no change. In Garnier and Schneider's case a bloody diarrhea took place during a phase of relative apyrexia, but the drop in the temperature was progressive.

In the case I have reported there was a notable drop in the temperature—from 104° F. to 101° F.—on the day before the rather severe melena, while two days before the enterorrhagia the temperature fell from 103° F. to 101° F. in the evening.

Hence, it is clear that in some cases a more or less sudden drop of temperature may occur on the days immediately preceding the hemorrhage. This drop, which takes place without being accompanied by the usual phenomena of pneumonic crisis and without any marked change in the local symptoms, should warn the physician.

When the hemorrhage has occurred, the temperature also may present some changes other than the hypothermy succeeding large losses of blood with phenomena of collapses. In my case the chart presented the inverse type on the day of the melena and on that of the enterorrhagia, and the pulse rate constantly followed the temperature. In Tourtoulis-Bey's case the pulse went up to 135 with a temperature of 103.5° F. the evening before the enterorrhagia. Rathery and Chauffard's patient had a pulse rate of 145 with a temperature of 102.2° F. on the day of the hemorrhage and after this the pulse became imperceptible although the temperature fell, both being very bad prognostic signs.

The blood pressure, taken with Pachon's instrument, during the hemorrhage in my case was rather weak with a low minimum. No reference is made to the blood pressure in the other cases here mentioned. It should be recalled, however, that a number of observers—Gilbert, Castaigne, François and Raynaud—have noted that the pressure is somewhat raised at the onset of pneumonia, while in the phase of full development there is a manifest hypotension which, with pulse and temperature, is important from the viewpoint of prognosis.

These hemorrhages in pneumococcal infection, whose general characters have been outlined, offer a particular physiognomy according to whether they occur in the form of hematemesis or enterorrhagia. The ratio of hematemesis offers to intestinal hemorrhage is as two to seven, or about twenty-seven per cent.

Referring to my case, the peculiarities of the particular phenomena observed are interesting. Melena occurred six days after patient entered hospital, a week later the enterorrhagia took place in a male presenting an acute infectious process, with a high temperature and scanty urine, although there was no appreciable organic localization that could be detected by ordinary clinical investigation.

The condition resembled typhoid, but after a Widal TAB test and several hemocultures on broth and bile obtained by doudenal tubage with negative results, a positive Rivalta was obtained on June 30th, and pleural puncture withdrawing pus containing a pure culture of pneumococcus settled the diagnosis. A pure culture of this bacterium was found in the urine at the same time. Regardless of the localization of the pneumococcus in numerous viscera the patient entered into convalescence after an illness of three months.

Traumatic Rupture of the Spleen

HARRY KOSTER, M.D., F.A.C.S.
Brooklyn

Traumatic rupture of the spleen without injury to any other viscus is sufficiently rare in itself to warrant the report of a case. Such splenic injuries almost invariably present themselves as lacerations of the organ. Infrequently is the spleen fragmented. The case reported belongs to this latter class.

CASE.—Harry H., aged seven, male, white, family history and previous personal history irrelevant, was struck by an automobile on August 12, 1921, at 4 p. m., and one of the front wheels passed over his abdomen.

About fifteen minutes after the accident he became semiconscious, vomited repeatedly and in his lucid intervals complained of thirst and pain in the abdomen. He was brought into the Brownsville and East New York Hospital at 8 p. m.

Physical examination revealed an anemic child in some shock, with shallow, sighing respirations, com-

plaining of thirst and pain in the upper abdomen. Temperature 101°, pulse 110, respirations 32. Mucous membranes pale, abdomen boardlike with marked tenderness in the left hypochondrium, liver, kidneys and spleen not palpable. Tympany in the centre of the abdomen, dullness in the flanks, no obliteration of liver dullness. Bladder catheterized and clear urine obtained. Blood count, erythrocytes, 2,500,000; leucocytes, 12,200; hemoglobin, 35 per cent. A provisional diagnosis of ruptured viscus was made and the patient operated through a right rectus incision. A large amount of fresh blood was found in the abdominal cavity. Two pieces of spleen found loose in the pelvis were removed and the remainder was found still attached to the splenic pedicle. The pedicle was ligated and a hypodermoclysis begun, after which the remaining portion of the spleen was excised. The free blood was wiped out with lap sponges and the abdomen closed without drainage.

The patient received 350 c. c. of saline on the table, and then at 12:30 a. m., 275 c. c. more and again at 6 a. m. another 400 c. c., each time by hypodermoclysis.

From then on he had an uneventful convalescence with the exception of the development of signs of a left pleural effusion on the 22nd, which disappeared spontaneously by the end of the month. Sutures were removed on the 21st, showing primary union and the patient was discharged on September 1, 1921.

The urine reports were negative throughout excepting for traces of albumin which persisted throughout the convalescence in the hospital. Blood counts were taken as follows:

	Hemoglobin	*Red*	*White*
August 13, 1921	35%	2,500,000	12,200
August 16, 1921	42%	3,000,000	11,500
August 22, 1921	53%	3,200,000	19,000
August 24, 1921	51%	3,400,000	26,000
August 29, 1921	55%	4,200,000	11,000
September 29, 1921	55%	4,000,000	11,300

It was interesting to note that the differential count showed a gradual diminution in the polynuclears and an increase in the small lymphocytes.

Two months after the operation the patient exhibited enlarged lymph glands all over the body; particularly prominent were the cervical and inguinal glands. Two years later there was no evidence of glandular hypertrophy, at which time he was in good health.

The prime motive for reporting this case is to take advantage of the opportunity to elaborate upon two important conclusions which can be drawn from it, and also to discuss the value of the spleen to the human economy.

In deciding for or against operation in cases of abdominal traumatism, an important factor is that part of the history which deals with the means by which the injury was sustained. If all patients receiving abdominal traumatisms were to be treated expectantly until well developed symptoms of visceral damage were noted, and then laparotomy performed, much valuable time would be lost in many instances where operation would reveal ruptured intestines with beginning peritonitis. An accurate history of an injury inflicted by a great force would immediately predispose towards operating rather than temporizing, even though the physical signs warranting exploration were not absolute.

The immediate prognosis in all cases of traumatism should be guarded and whenever possible, the patient should be kept under observation in a hospital for twenty-four hours. In this instance the patient was sent away from one institution without a release, and a practitioner attempted to assure the relatives that there was no cause for apprehension.

This boy is now deprived of his spleen. How he is going to combat the shocks of life depends upon the value of the spleen to the body. The spleen is the largest lymphoid structure in the body. It has been shown that there is a marked increase in the number and size of lymph glands following splenectomy. Because of this relationship and also because the spleen becomes enlarged in acute infections and intoxications, it would seem that it acts as a barrier to infection protecting the body against toxic invasion. It follows then, that splenectomized persons are more likely to succumb to infections. Clinical experience does not bear this out, probably because the loss of the spleen is compensated for by the hypertrophy and hyperplasia of the lymphatic system.

The erythrocytes which have completed their life cycles are destroyed in the spleen and their iron is temporarily stored there. The spleen in itself has but slight hemolytic power, but is powerfully activated by liver extract. After splenectomy it has been observed that the lymphatic glands have an augmented ability to destroy red cells.

The spleen aids in the formation of leucocytes. This function is also taken over by the hypertrophied lymphatic glands after splenectomy.

The spleen undergoes rhythmic contractions about once a minute. These contractions help maintain lymph flow. It also begins to enlarge shortly after a meal, reaching its maximum in five or six hours, after which it gradually resumes its normal size. This enlargement is supposed to result in the accommodation of considerable portal blood in the effort to regulate the blood supply in the splanchnic region. Xanthin, adenin, guanin and uric acid have been found in the spleen and for this reason it has been suggested that the spleen is concerned with metabolism.

In man a large number of the cells classified as belonging to the reticuloendothelial system are found in the spleen, namely, the reticulum cells of the pulp, endothelial cells of the blood sinuses and the splenocytes. The cells of this system, besides their activity in the processes enumerated above, are intimately concerned with the formation of bile pigment, storage of lipoids, metabolism of phosphorus, formation of immune bodies, ferment production. These processes are all of considerable value to the body, but fortunately the cells of the system, situated elsewhere than in the spleen, as, for instance, in the cortical nodules of lymph nodes, lining cells of the lymph sinuses, Kupffer cells of the liver capillaries, the lining cells of the capillaries of the bonemarrow, the adrenal cortex and hypothysis, can and do compensate for the loss of the spleen, through hypertrophy.

Clinically its removal does not materially affect the welfare of the person. A few cases have been reported in which the spleen was congenitally absent. Therefore, although an organ of considerable importance to the body, in the face of injury with severe hemorrhage the most conservative form of treatment is splenectomy.

Historical Medicine

Ancient and Modern Medical Heresies

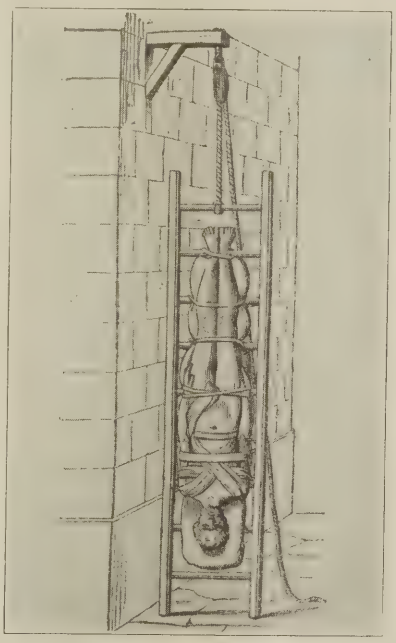
JONATHAN WRIGHT, M.D.
Pleasantville, N. Y.

In the last paper I was busy tracing out the germ of homeopathy and Christian science beyond the time of Galen for most medical heresies like most heresies of any kind have in them some germ of truth which has its affiliation with some fundamental basis of human thought and no human theory is without an element which, pursued to its ultimate analysis, leads us into a blind alley of absurdity. We shall find these things fully illustrated in what I shall have to say of chiropractise, or however the art is to be called. A number of years ago I was interested in the traces I found of it in the Hippocratic books, and this interest later found some expression in the pages of this journal (1). In the treatises of Hippocrates on fractures and dislocations there are some curious implications and connotations which it will not be devoid of interest to follow into Galen's writings. To refer as briefly as possible to this former interest (2) I will repeat that in several places in the books, both genuine and those supposed to be the work of another author or authors, the pathology involved a supposed dislocation of a cervical vertebra—the vertebra dentata—"in the course of a fever when the neck becomes suddenly distorted and the patient can hardly swallow and there is no tumefaction, it is fatal." This is the language of the Prorrhetics and Coan Prenotions (3a), but in the Aphorisms it reads a little differently, "incurvation of the spine at the vertebra next the occiput" (3b). I take it from Adams's commentary on this that a hundred years or so ago Sir Charles Bell described a disease Adams thought might be it under the head of "Inflammation and laceration in the Atlas and Vertebra Dentata" (4). It is supposed by Adams that this first book of the Prorrhetics and the Coan Prenotions are both older than Hippocrates II and one theory largely held by many critics is that the *Aphorisms* are compiled from the written works or oral instruction of the Master, but from a passage in the book on the Articulations (3d), which all critics ascribe to him, the view evidently to be inferred is that the second cervical vertebra can not be lacerated or displaced in this way without causing immediate death and in the *II Epidemics* I do not see as Littré seems to think he commits himself to this belief at all. Strange to say this belief became recrudescent in the time of the great French lexicographer (3c). It is then no further cause for wonder that at this time of Littré and Adams there was no criticism of the great frequency with which Hippocrates apparently met deviations of the spinal column from its normal shape due, as he thought, to partial dislocation of the body of one vertebra on that of the other, but he explicitly says that it is rarely the case that one or more of the vertebra are torn from their articulations or experience much displacement, "for the displaced vertebra would compress the spinal marrow and induce insensibility of many great and important parts." Practically the same verdict is given in the Mochlicus (No. 37). He is very sceptical in both these general treatises of any attempt proving successful to replace a dislocated vertebra and it would seem very singular if he should believe the second cervical vertebra could suffer such an accident in quinsy or diphtheria, about which the discourse is, where Littré seems to think he means a dislocation.



For Spinal Curvature
(Littré's *Hippocrates*)

We are for this reason, if for no other, driven to the conclusion that the author of the *II Epidemics and Articulations* and the Mochlicus was not the author of the *Aphorisms* and he not only did not write the *Prenotions* and the *I Prorrhetics* but he did not approve of the passages referred to, if they were in existence before him.

It would seem then that Galen was correct in his surmise that Hippocrates knew the function of the spinal cord and perhaps the final origin of the nerves of motion and sensation in the brain, though perhaps this is not here to be implied. Galen's master Pelops (5a) knew the nerves came from the head as did Erasistratus, but the latter, at least when young, thought they originated in the meninges and not in the brain proper, while even Galen in his day, four hundred years later, thought it worth while to demonstrate and record experiments of his own clearly, it seems to us, proving the cerebral origin of the nerves. Possibly they were known to Alcmaeon two hundred years before Aristotle. Galen even supposes (5b) Chrysippus, the preceptor of Erasistratus, knew the nerves came from the head yet had the folly to think it was the heart supplied them with power. The idea that the nerves had their origin in the meninges was due to confounding them with tendons and fibrous structures. Aristotle

thought they started from the fibrous structures of the heart and others besides him that the arterial coats at their ends gave rise to them, and these vessels carried the control of the muscles.

We can not believe therefore Hippocrates had any correct conception of the function of the nerves, which first after him Herophilus and Eudemus carefully described, perhaps in the early years of Erasistratus (5c). Although Aristotle made some distinction between the marrow of the bones and the marrow of the spinal cord, it is not much and despite the fact Galen seems to think (5d) Plato may have made a significant deduction neither he nor Aristotle had any appreciation of its function, though the latter noted its continuation with brain substance. Primitive man, even the butchers and cooks, as Galen is fond of saying, knew as much. In section No. 45 of the Articulations (3d) Hippocrates gives a little space to the description of the spinal cord and says "as for the spinal marrow itself, what its coverings are, whence they spring, where they end, and with what they communicate and what the functions of them are I will explain," but the few words which follow neither the translation of Littré nor the commentary of Galen in the least explain, nor do the translation and remarks of Adams enlighten us, but the latter seems to infer that Hippocrates had written some anatomical work which has not reached us. So far as Littré's text goes it is only his intention to write it he announces, "they will be described in another work," he says of the spinal structures. The work on The Flesh (3e) gives more succinctly than Aristotle (6) intimation of the connection of the spinal cord with the brain and distinctly says it is not like the marrow of the bones. Adams places the date of this spurious book of the Hippocratic Corpus after Aristotle, but neither in this nor in other late books, manifestly spurious, is there any hint of its real function, while the reference in *Articulations* is indubitable evidence that Hippocrates II, if he wrote anything in medicine, ascribed correctly the cause of paralysis of the muscles of the body to injury of the spinal cord. From the time of Hippocrates to the time of Galen, whatever may have been done on the nerves in the meanwhile, we have no such unequivocal evidence.

The conclusion seems to be inescapable that Hippocrates II knew what dislocation of the spinal column portended and I may be excused for thus adducing the evidence on which it rests at a little length because it throws light on his decided views as to the value of manipulations of the spine by the chiropractors of his day. He was not so vehement and unphilosophical as we are, nor so vitriolic as Galen when he disagreed with any one. Some supposed that complete dislocation forwards is easily remedied. "Many are ignorant and profit by their ignorance." These are the ones we charge with knocking now not unsuccessfully at the doors of the profession for admission but there can be no doubt the activity in the regular profession today, in bloodless surgery, in physicotherapy for instance, is a reflex excited in men of medical science from without. But Hippocrates does not say these men are charlatans and frauds, he even says some of them believe these anterior dislocations do not stand in need of reduction, but get well spontaneously. "Such a case is not to be reduced by succussion or by any other method, unless we are to cut open the patient and then having introduced the hand into one of the great cavities were to push outward on it from within, which one might do in the dead body, but not at all in the living."

Galen seldom contradicts Hippocrates and never speaks of him but with reverence, with bated breath as it were, never ridicules or addresses him across the ages with familiar jibing—I know of no one else, except possibly Plato, of whom without exception this is true. Of Plato he had borrowed more than of Hippocrates in this book on their theories. Indeed Plato has more influenced the trend of his speculative thought than Hippocrates, because the latter deals with supposed realities and facts which are always changing, while Plato deals with idealities which are eternal and in essence unchanging. When Galen does speak in correction of Hippocrates it is in a deprecating manner, not in the modern patronizing manner we use toward our elders. To compare its manners otherwise unfavorably with those of Galen is too severe a charge to bring against the courtesy of the modern profession. For we are all only half way men, *nihil nimis,* nothing too much in the way of praise or blame for those within the pale. Whether within the pale or not, Galen fell on his knees before his admirations and went after his opponents with a club. He does not, let us say in extenuation of some of his polemics, pretend he has more knowledge because he lives in the present instead of the past as is the modern patronizing manner. Knowledge for him has not increased, evolution is out of the question, he is a *descendant* of Hippocrates, he has not ascended from the Master's lower level. Things have changed of course, but things that were important for Hippocrates at the time he wrote some five hundred years before, possibly made him forget for the moment to mention a point in the differential diagnosis of downward displacement of the shoulder. The hollow left above was pronounced and really for a close observer could mean only one thing, but one less careful than Hippocrates might mistake the depression due to a fracture of the acromion process for a dislocation of the head of the bone. Something in this manner he talks of the Master, quite differently of most others. He tosses only bouquets at Hippocrates and only bricks at Chrysippus and Asclepiades.

Galen believed a good many books of the Hippocratic Corpus genuine, which more modern criticism has rejected. The passage in the Prorrhetics of Hippocrates as to the displacement of the odontoid process causing laryngeal and pharyngeal obstruction, which was probably diphtheria, he accepts as coming from the hand of the Master (5e). As to the displacement of the other vertebræ, Galen quoting Hippocrates has no doubt of its occurrence and he differentiates conditions of dislocation from those of fracture, saying the former are easily treated and the latter destructive. In other words all the displacements of the spinal column causing compression of the cord he calls fractures, but Hippocrates does not. This is an instance where Galen is disingenuous, this time out of reverence, not malignity. In order to agree perfectly with Hippocrates he makes Hippocrates say something which does not exist in the text we have. However they both agree that displacement posteriorly is

not serious. They both in this seem to regard the greater or less prominence of the spinous processes and the lateral deviations of the spine as dislocations. Some of these we admit can be easily benefitted by exercise and posture, some of them may be much improved by more difficult mechanotherapy—by rubbing and pulling at them—never. Hippocrates says nothing as to the symptoms in these cases. He was evidently thinking of the naked backs he saw in the palæstræ and so was Galen, who in his younger days was a surgeon to the gladiators at Pergamum. Our ideas in regard to fracture and dislocation of the spine have frozen into formulæ which mean very largely if not entirely acute surgical cases. Deviations of the spine in our modern terminology do not mean dislocations, certainly not disarticulations, but Hippocrates and Galen had something more in view than the rising and sinking of the spinous processes of the vertebræ and the lateral inclinations of the spinal column in our sense. They postulated the possibility of a very much greater slipping of the surfaces of the vertebral bodies on one another without compression of the cord than we are accustomed to think of. We see this in the way Hippocrates speaks of those we would call chiropractors, so far as their views of the mechanism of the spine is concerned, and we see it also in the readiness with which Galen accepts (5e) the "dislocation of the vertebra dentata" in cases of laryngeal dyspnœa.

Medicine According to the Talmud

SOLOMON R. KAGAN, M.D.
Springfield, Mass.

INTRODUCTION

The Talmud is a commentary on the Bible, and also an encyclopedia. It includes snatches of jurisprudence, history, morals, ethics, mythology, astronomy, mathematics, philosophy, theology, medicine, anatomy and botany. It was compiled by a number of Jewish scholars as a tradition transmitted orally for centuries and at the end of the fifth century was finally cast into definite literary form as a collective labor of many generations. It contains six portions (called Sedarim), sixty-three treatises, and 524 chapters. The whole work fills 2,947 folio leaves. The language of the Talmud is Aramaic or Chaldee, but the additional matter is principally in Hebrew. The text on the single pages is kept uniform with the previous editions to facilitate the use of references.

Some of the Talmudic sayings and statements have not the consensus of Talmudic opinion, but merely represent an individual view. Many modern philosophical theories, hypotheses about physics, chemistry, anatomy, astronomy, and medicine are often found in the Talmud. For example, what is now known as the Darwinian theory of the origin of the human species was previously discussed in the Talmud. Rabbi Judah said: "Man was created a live animal with a tail, but it was removed on account of his honor." As a religious man he saw in God's creation of man the highest form, and therefore his solution bears a religious seal and character.

Much attention was given by the Talmud to medicine, to study of principles and theories which were later discussed by the modern scientists and clinics. The erudition and sagacity of the rabbis was great and they evolved a system of treatment and hygiene which in scope and excellence stands far above the period of civilization in which they lived.

The wealth of Talmudic medicine is best revealed when it is compared with the methods of modern medicine. Everyone who is in touch with therapeutic literature will have a conception of the multitude of new methods of treatment which are brought forward, some of which prove valueless, but many of which are exceedingly useful. In addition to new methods, a constant modification of old ones occurs, showing an increase in their efficiency. The methods of treatment applied by the Talmudists are worthy of study. Many views of the ancient Talmudic physicians, hygienic rules and methods of treatment have a certain scientific value.

PATHOGENESIS ACCORDING TO THE TALMUD

In the Talmudic epoch the people regarded disease as a punishment of God for sins. All epidemics called for repentance. They believed that babies died because of the bad conduct of the adults (1). Rabbi Jehuda Hanasi's calf was taken for slaughter. It ran for protection under Rabbi Jehudah's clothes. The rabbi said that it was destined by God for slaughter. The rabbi was therefore punished with a severe intestinal malady for a long period.

Later his maid wanted to throw out a small kitten, but he took pity on the animal and interfered. The Lord cured him, and the Rabbi recovered entirely (2). Death followed not from paralysis of the vital centres, but rather because the angel of death according to God's command took the soul by means of poison drops. The Talmud says: "There is pestilence in the city, so do not walk in the middle of the road, for the angel of death walks thereon" (3). By repentance and prayer one avoided the angel of death. Rabbah studied continually. When the angel of death received an order from God to bring Rabbah he

could not conquer him, because Rabbah's spirit was undefeatable. But in the moment when Rabbah stopped intellectual and spiritual activity and began to take care of his body, the angel of death took his soul (4).

The Talmud suggests that the causes of diseases are: excess, cold, wind, heat, climate, impure food, bad habits and uncleanliness (5). Unhygienic conditions were considered the principal cause of maladies. Rabbi Samuel says: "Uncleanliness of the head causes infection of the scalp and eyes; uncleanliness of the clothes produces discomfort and nervousness; uncleanliness of the body causes skin diseases and disability" (6). "When a stain is found on the clothes of a scholar he is worthy of the death penalty." "Maladies are prevalent in unclean places" (7).

Unripe fruits and contaminated water were recognized as dangerous and as etiological factors of many severe diseases (8). Overeating and impure food caused stomach disorders (9). "Three things cause the weakness of the body: fear, travel and sin" (10). "Worries and sighing wear out the human body" (11). "Hemophilia (abnormal tendency to hemorrhage) is hereditary" (12). "Overmental work and laziness produce neurasthenia and weakness" (13). Running and jumping are believed to induce certain diseases (14). The solution of continuity of the spinal cord brings limping; softening of the spinal cord causes tremor of the head (15). The Talmud regards minute organisms and insects as the causes of certain diseases. It is said: "There are many germs and insects." "The harm producing minute organisms are everywhere in abundance, if we would see them we could not exist" (16).

METHOD OF DIAGNOSIS ACCORDING TO THE TALMUD

The diagnosis of diseases was made on the basis of anamnesis, palpation, observation and sometimes by the application of physical and chemical reagents. They had a number of wonderful reagents composed of seven chemicals which served as a blood test (17). The diagnosis of stomatitis was made on the ground of the redness, swelling and tenderness of the inflamed area. The rabbis and the priests, the most educated and trained, were recognized as specialists in medicine as well. In cases in which the diagnosis was doubtful they isolated the patient for observation. The diagnosis of skin diseases was decided on the ground of the size, shape, temperature, exudation and color of hair of the sores. The clinical observation took from one to three weeks (18). The Talmud suggested that a thorough examination was necessary for correct diagnosis. "A physician who treated without examination brought harm." "A physician who heals for nothing is worth nothing" (19). "Even some of the best physicians may deserve punishment because of incorrect diagnosis and treatment" (20).

The Talmud considered that the prognosis of an illness depended upon the cause and location. Internal diseases were more serious than external (21). The most dangerous were: angina pectoris, meningitis, inflammation of spinal cord, and gallbladder disease, but they, however, had a mild course in animals (22). Heart trouble was recognized as a grave malady, because the function of all organs depends upon the heart (23). Open wounds were treated as a serious disease; cancer was considered dangerous (24). Eye diseases were also regarded as grave (25). Perforation of the heart, esophagus, stomach and volvulus were believed to be fatal, as was injury of the spinal cord (26). Atrophy or abscess of the kidney caused death, but extirpation of the spleen, ablation of the uterus and accumulation of transparent fluid in the kidney were not considered fatal (27). The Talmud said: "Rather any trouble than sickness of the bowels; rather any pain than pain of the heart; rather any disorder than a disorder of the head; rather any evil than a bad wife" (28).

HYGIENE ACCORDING TO THE TALMUD

The Talmud considered hygiene to be of the utmost importance. Cleanliness, bathing, proper food, regular life, isolation of infected patients, and prevention of contagious diseases were urgently advised. "Be careful of the flies near the contagious patient," said the Talmud (29). "The amputated organs of the contagious should be buried" (30). The patient suffering from leprosy is strictly isolated, and he should declare himself as afflicted. If one had been in close contact with a leper he was held under suspicion during the incubation period (31).

According to the Talmud, to drink water flowing through filthy places was forbidden on account of the danger of contamination (32). It was also forbidden to partake of a dish of water, wine or milk left uncovered because of the danger of a hidden snake entering and drinking the liquid, thus polluting it with snake venom or some poison (33). The Talmud, too, warned against living in a town where there were neither physicians nor bathing facilities (34). It advised washing the hands before each meal, and the lips and mouth after meals, to prevent diseases of the teeth and gums; but, as hygienic precautions would not be practised by ordinary people, the Talmudists assembled these beneficial measures as a code of laws, which has an impelling religious significance. Thus many ritual actions have their origin and basis in hygienic principles.

"The Torah is to take care of the public health and hygiene," said the Talmud (35). Heat and some drugs were used for disinfecting purposes. "Water suspected of containing germs should be boiled before drinking" (36). Rabbi Assi cured the shoulder of R. Abuhu by cauterizing the wound (37). "Do not keep money in mouth, and do not put any food in unclean places" (38). "Do not drink from unclean glasses" (39). "The clothes used in the kitchen might not be used in the diningroom" (40). "Unclean hands cause illness" (41). "If you taste the soup do not return the remains in the pot"' (42).

To prevent an offensive odor from the mouth plenty of fresh water to drink and frequent mouth washing were recommended (43). The food for eating must be fresh and prepared in cleanliness and in proper form for the purpose of digestion. Rabbi Eleazer says: "Do not live in a town where there are no vegetable gardens" (44). "Excessive sitting is harmful for the stomach; excess of standing, harmful for the heart, and excess of walking, harmful for the eyes; therefore one should arrange to sit, stand and walk in equal proportions" (45). Care of the stomach was considered the basis of health. "The food must be easily digested" (46).

In accordance with this rule the Talmud warns

against eating unripe fruits or some kinds of food difficult to digest. The Talmud discussed the historical fact that out of Sancheriff's forces, when he besieged Jerusalem, 185,000 men died in one night. Rabbi Simmon said that eating unripe fruits was the cause of their death (47). Some epidemics were explained by the Talmud as the result of the use of impure water. Drinking of pure water prevents stomach trouble. "Eat and drink less, and spend more on your home and clothes" (48). "Who eats slowly lives longer" (49).

The regulation of mealtimes was regarded as an important factor. "When one gets his breakfast at the proper time, he becomes healthy and active," says the Talmud (50). The Talmudists recommended having breakfast at a regular time, depending on the profession and the habits of the individual. The rabbis believed that the first hour of the day was the proper time for breakfasting for Lydians who were cannibals; in the second hour robbers were to eat; in the third hour heirs; the fourth hour was the proper eating time for people in general, the fifth hour for laborers, the sixth hour for scholars and from the last hour onward eating was like throwing a stone into a barrel, more injurious than beneficial (51).

Rabbi Chisda said: "A man who attends school, and has not sufficient bread, should not eat herbs, because it creates hunger. I myself have never eaten herbs, neither when I was poor nor when I was rich. When I was rich I ate meat and fish in place of vegetables." He said again: "A young pupil who lacks food should not eat a little at a time. He should wait until he can accumulate sufficient for a hearty meal, and then eat. When I was poor I never ate, until I could put my hand in the basket and find sufficient to satisfy my hunger" (52). "To eat and drink standing is harmful" (53). "Do not teach your son to eat meat and drink wine" (54). "Do not eat immoderately" (55). "Wine in small amounts is a remedy; in large amounts it is poisonous" (56). "The following seven objects are beneficial if used moderately and harmful if used excessively: travel, luxury, work, wine, sleep, warm water, and venesection for medical purposes" (57). "Green colowort, sea radishes, the water from sisin (a Syrian plant), the stomach, the uterus (of cattle), and the raw meat of a cow are good for all diseases" (58). "After meals it is healthy to take a short walk." "Do not speak during a meal, because the food can enter the trachea which is dangerous" (59). "Ten things are detrimental to the sick, viz., meat of an ox, fat, roasted meat, poultry, fried eggs, almonds, a haircut, a bath, cheese, and liver. Others add yet nuts and gourds" (60).

The Talmud teaches that the quality of food is more important than the quantity. Discussing the value of vegetables and meats, the rabbis made a comparison between two persons, namely, Pekach b. Remale and Cheskia. The former had used meat almost entirely, while the latter was a strict vegetarian. Nevertheless, Cheskia conquered Pekach b. Remale in battle, because Cheskia, who observed a moderate life, avoiding too much food, was slender, strong, and active, but the excessive meat only made Pekach b. Remale fat, weak, and slow (61).

The Talmud suggested that the food must be varied. Carbohydrates and vegetables were regarded as unsatisfactory, but together with fats they were recognized a source of energy, producing power (62).

Concerning different food values the Talmud pronounced as suitable milk, meat, fish, eggs and vegetables. According to the opinion of Rabbi Janai any food having the same weight as an egg, when its food values were compared, will be much lower in caloric standard than the egg itself (63).

(*To be concluded*)

An Historical Analysis of Laënnec's Scientific Work

CHARLES GREENE CUMSTON, M.D.
Geneva, Switzerland

(*Concluded from page* 390)

Laënnec was the first to study the disease from the right point of view and showed that the tubercles in the pulmonary parenchyma were the pathological elements of the affection. With the stethoscope and necropsies Laënnec developed the diagnosis of this disease and also showed that although in his day pulmonary phthisis resisted all therapeutical measures, there were some instances in which complete cicatrization of the lesions occurred followed by recovery from the disease which had until then been regarded as absolutely incurable.

The results of Laënnec's researches on tuberculosis naturally underwent certain more or less important changes, especially about the middle of the last century, which must be referred to. Laënnec believed that it was impossible to diagnose tubercles at their onset and it remained for my compatriot, Dr. James Jackson of Boston to show that when the pulmonary parenchyma becomes more dense on account of the presence of tuberculous changes the expiration which in the normal state is hardly sensible to the ear, increases in intensity and finally equals or may even conceal the inspiratory sounds. This sign was exceedingly important since it indicated an induration of the lung long before percussion could give any diagnostic information. This happy discovery of the Boston physician was greatly enhanced by Fournet who pointed out the difference of the duration between inspiration and expiration at the time when the tubercles began to develop. He studied these two physiological phenomena with great patience and in his book on the diagnosis of pulmonary tuberculosis will be found for the first time a complete description of the early diagnostic signs of the disease.

Under the term of harsh respiratory sounds (*bruit respiratoire râpeux*) he describes a phenomenon present when the tubercles are in a state of crudity and regarded this pathologic sound as a pathognomonic sign of their development.

In his *Reserches sur la Phthisie,* Laënnec gives descriptions of tuberculous ulcerations of the trachea, larynx and especially of the epiglottis. He was also the first to call attention to lesions of the gastrointestinal mucosa in this disease. He likewise formulated a rule that he considered absolute, namely, that when tubercles are found in organs other than the lungs, they will invariably be found in the pulmonary parenchyma.

Laënnec's researches on diseases of the heart are not as complete as those on the lungs and therefore are less important, but what he has written on cardiac pathology is done with the same perfection as his other contributions. He used the stethoscope for their diagnosis, but his efforts were not always crowned by success. Had Laënnec been alive at the time of the great discussion which took place in 1831, on the origin and cause of cardiac sounds it is more than likely that he would have been able to add much to the then obscure notions prevailing in respect of cardiac physiology.

As a pathologist, Laënnec, unlike Bichat, did not generalize. He was content simply to describe what he saw; he brought together and united in a single group anatomical changes having several things in common, but he invariably broke away from this system if great similarity was wanting between them.

From Laënnec's day to our own the treatment of diseases of the lungs has steadily progressed, thanks to diagnosis which is the essential basis of therapeutics and it is clearly evident that our thanks for this progress are first of all due to this great French physician.

Contributors to the Science of Medicine

Marie Francois Xavier Bichat

Bichat certainly is an outstanding example of the saying that "those whom the gods love die young." He died before he was thirty-one and had crowded into the ten working years of his life enough original investigation to ensure for him a place among the immortals of medical science.

Xavier Bichat was born on November 11, 1771, at Thoirette, in the department of the Ain. His father was a doctor of medicine of the University of Montpellier and to his instruction his son's early knowledge of medicine may be attributed. He had a brilliant career in arts. Bichat received his anatomical training at Lyons. At this period the study of surgery had come to the front, owing to the fame of Desault the great French surgeon of the day. To this study Bichat applied himself working under the chief surgeon of the Hôtel Dieu of Lyons, Marc Antoine Petit.

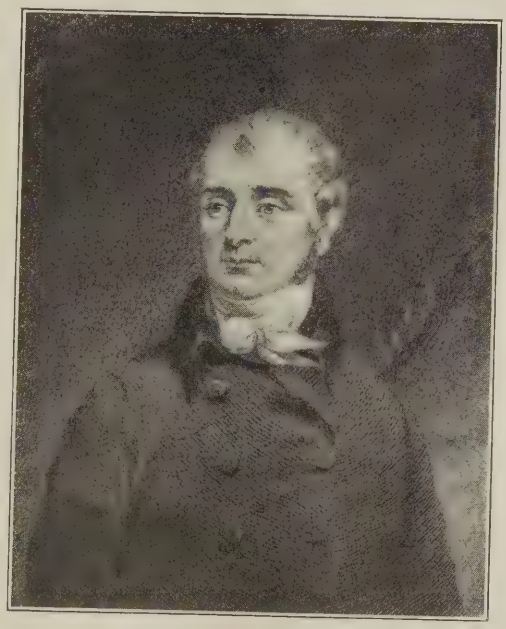
The revolution obliged Bichat to leave Lyons and he went to Paris where a larger field and one more adapted to his powers presented itself. In keeping with the trend of the times his views were directed to military surgery, and accordingly he attended the Hôtel Dieu of Paris and heard the lectures of Desault. A practice was established among the attendants of this surgical course, that pupils were selected to make an abstract of the lecture of the day, which was delivered in the presence of the second surgeon.

An accident in a great measure determined the future fortunes of Bichat. The pupil being absent whose turn it was to deliver the abstract of a long and important lecture on fractures of the clavicle, Bichat offered to take his place. He was blessed with a wonderful memory, and the purity of his style, the precision, the clearness of his ideas, the scrupulous exactness of his conclusions announced the born teacher rather than the student. Desault heard of the lecture and became acquainted with Bichat. So greatly was Desault impressed with him that he immediately offered to direct his studies, to receive him into his house and to treat him as a son. The foundation for Bichat's reputation was thus laid. Desault took him everywhere, to his public and private patients. Bichat became not only an assistant in his operations, but was also engaged in helping his chief in his literary work.

Desault died very suddenly in 1795 and Bichat was left to depend upon his own resources. In the winter of 1797 he commenced his career as a lecturer, and, not calculating upon a large class he restricted himself to a small suite of chambers. He had not even a dissecting room; he confined himself to simple demonstrations but in these his physiological views developed so rapidly that he determined to give a course of operations at the end of his anatomy lectures, a very unusual proceeding at that time and only undertaken by the most practised surgeon. His success, however, well justified the experiment, but the labor attending these exertions affected his health so severely that he suffered from a severe attack of hemoptysis. Nothing daunted, on partial recovery, he established a theatre for dissections, which was attended by more than eighty pupils.

Bichat then resolved to work out a system of anatomy founded on the observation of M. Pinel that disease consisted in the alteration in the tissue of an organ. This theory appears to have given to Bichat the idea of studying anatomy by a separate consideration of those structures which enter into the formation of the different parts. Up to this time the membranes had not formed any special subject of investigation; they had been examined and described

in connection with the different organs, but never independently of their association with other parts. From the days of Haller to the time of Bichat the whole of the membranes had been referred to a common origin, the cellular membrane. Bichat recognized that however true in a general relation this arrangement might be, yet upon examination it was found to be under various conditions quite erroneous. He was the first author who ventured to treat of the subject under more various and particular points of view. Anatomy, physiology and pathology have all advanced by the work of Bichat and it has been said that many of the improvements in these departments of science are in some degree attributable to the researches and classifications of this very able philosopher. His views on this subject have been published in a distinct treatise entitled *Traite des Membranes,* the first edition of which was published in 1800. The second volume of the *Mémoires de la Société Médicale d'Emulation,* of which society he was an active member, contains his early papers on this subject. Three other memoirs by Bichat are inserted in this volume: the first on a new trepan, so arranged as to raise or depress the crown at pleasure by means of a screw; the second, on the impossibility of any displacement occurring when the humeral extremity of the clavicle is fractured; and the third, on a new manner of removing polypi by the ligature.



Marie Francois Xavier Bichat

Bichat also was an original and earnest worker in physiology and published his views in the *Recherches Physiologiques sur la vie et la Mort,* and in the *Anatomie Générale* he put down his views of a new system of anatomy. This was followed by a system of descriptive anatomy. Then an edition of the works of Desault, with many editions by the editor.

In 1800 Bichat was appointed physician to the Hôtel Dieu. He was indefatigable in examining the bodies of those who died under his care and under the care of his assistants and is said to have examined more than six hundred bodies during one winter. Materia medica also engaged his attention. He felt the necessity for classing medicines according to the influence which they exercised over the vital properties. He was assisted in this inquiry by no fewer than forty pupils who, under his directions, gave daily reports on their work, the progress of which was announced in a regular public lecture delivered by Bichat.

He died when in the midst of his fury for knowledge, a martyr to science, presumably as a result of an accident. He fell in descending a staircase at the Hôtel Dieu, was greatly bruised and sustained a slight concussion of the brain. He passed away on the fourteenth day after the accident on July 22, 1802, in the thirty-first year of his age.

Bichat fell a victim to his zeal for science and died when his reputation was at its height. His loss was regarded as national. When Corvisart communicated the intelligence of his death to Napoleon Bonaparte, then first consul, he remarked: *"Bichat vient de mourir sur un champ de bataille qui compte aussi plus d'une victime; personne en si pen de temps n'a fait taut de choses et aussi bien."* Ten days later the government caused his name to be inscribed, together with that of Desault, on a memorial erected at the Hôtel Dieu in their honor.

The life of Bichat has been written by Muisson and by Husson. An historical notice has been published by Pinel. Hallé delivered a eulogy before the Faculty of Medicine in Paris. Wrapped up in a consuming desire for knowledge, medical science was father, mother, and family to Bichat. Like many men of genius he seems to have been urged on by some inherent power over which he had no control, always searching for a goal which was never quite reached. In the few years that he worked to this end he added something to the sum of scientific knowledge and blazed a trail to point the way to others.

Bichat was of a very amiable disposition and was beloved by his colleagues, his students and all with whom he came into contact. He is said to have been a stranger to every and all of the baser passions. He was devotedly attached to his father. He was of middle height and while his countenance was agreeable it was distinguished chiefly by piercing and expressive eyes.

Bichat's head was very remarkable and Cloquet in *Traité d'Anatomie* has given a representation of his skill as a specimen of the Caucasian variety of the human race. In form it is singularly irregular, the left side projecting much beyond that of the opposite side. The sutures are also irregular, and the defect of symmetry is as evident in the interior as it is on the exterior of the skull. The forehead is particularly large and capacious.

The works of Bichat have been translated into various languages, and have gone through many editions.

Rima and the Surgical Cure of Varicose Veins.—Senator D. Giordano, in an address before the Third Congress on the History of Italian Medicine, made an interesting study of the theory of Rima on varicose veins. The surgical cure of varicose veins dates from the remotest antiquity, but is was almost forgotten when Rima, in the course of inspecting a hospital at Pavia in 1806, had occasion to examine a convalescent patient operated on by Cairoli, after the method of Home "for varicose veins of the leg by ligature of the saphena in the region of the articulation of the knee." He immediately put into practice this theory and in 1807 had operated on thirty-eight patients, with a loss of only three.—*Æsculape.*

Editorial Articles

SOME OLD VIEWS OF MEDICINE

In spite of the fact that the knowledge and practice of medicine of our forefathers was largely empirical, they possessed probably a practical and clinical knowledge of disease which they carried into effect not surpassed even if it is equalled by the practitioners of the present generation. Their knowledge was based on bedside experience and although their treatment, therapeutic and otherwise, was rough and ready, on the whole they reached successful results.

At one time bloodletting was part of the routine of general practice and it is likely that until it was abused the outcome was satisfactory. In the days when the men were large meat eaters and heavy consumers of alcoholic beverages, when acute gout was one of the most common diseases and high blood pressure and cerebral lesions occurred with comparative frequency, it was, perhaps, common sense practice to use venesection occasionally.

However, the practice was carried to excess and for quite a considerable period was the medical fad or obsession. Carried to the extent that it was some two hundred years ago bloodletting killed its tens of thousands. As Dr. J. D. Comrie points out in the *Glasgow Medical Journal,* November, 1925, this pernicious doctrine developed from Harvey's discovery of the circulation of blood and especially from the investigations of Boyle and those who showed that combustion and respiration were virtually the same process. This was the *phlogiston* theory advanced by Stahl at the end of the seventeenth century. This theory consisted of the idea that when a material wasted away in burning it gave off a hypothetical substance—phlogiston. In fever when this substance was apparently not escaping from the lungs quickly enough what was more reasonable than to get rid of it by removing it with the blood. Hence the process of bloodletting which had been moderate in ancient and medieval times, suddenly in the eighteenth century increased to alarming dimensions and continued to rule medical practice up to the middle of the nineteenth century. One of the most celebrated exponents of this method of treatment was Dr. Lettsom, who founded the Medical Society of London. He bled for every disease, including tuberculosis, and was so firm a believer in the merits of bloodletting that he is said to have hastened his own end by frequently bleeding himself when suffering from a wasting disease.

The most exquisite satire on this old time medical obsession was that of Le Sage in *Gil Blas* who makes the great Dr. Sangrado say, "Without more ado I will initiate you in the healing art of which I have been so many years at the head. Other physicians make the science to consist of various unintelligible branches but I will shorten the road for you and dispense with the drudgery of studying natural philosophy, pharmacy, botany and anatomy. Remember my friend that bleeding and drinking warm water are the two great principles, the true secret of curing all distempers incident to humanity." The custom of bloodletting went out suddenly and so great was the reaction against the practice that it was discarded entirely. As said before, it possesses some virtues when employed judiciously but as employed in the eighteenth century supplies a remarkable instance of how far a medical obsession and public credulity can go.

ADULT CHILDISHNESS

Two physicians, Dr. Joseph Collins and Prof. D. Fraser Harris, of Dalhousie University, have had it on their minds that modern adults are exceeding childish. Each expresses himself on the subject, and the articles appeared the same month of the same year, one in an American monthly, *Scribner's,* and one in an English review, *The Contemporary.* One bit of evidence is given by both (the season for straw hats), though otherwise there is no sign of collusion, and, doubtless, each was surprised on seeing the other's production. All things come in twos, as he who has served as hospital intern knows full well.

Physicians see much of humanity behind as well as in front of the scenes, and when two of them feel so moved to say something not very complimentary about their fellows, there must be good reason.

Of course we are all more or less grownup children. With one foot in the grave, we still have one in the cradle. We kick up considerable dust with our clumsy adult feet, but there ought to be some slight trace of the cloud of glory with which we arrived. We need to be childlike to enter the kingdom of heaven, though there is considerable difference between childlikeness and childishness.

Fraser goes to the bottom of his subject when he defines childishness as mental immaturity and, in particular, "the incapacity to grasp the universality of the doctrine of cause and effect. The *post hoc* is everywhere mistaken for the *propter hoc,* and this not only among the uneducated masses but among those whose training should have disposed them to think otherwise. The persistence of superstition in the life of today i

due mainly to two causes, one the receptivity and suggestibility of minds which have never grasped the meaning of causation, the other the perpetuation of the superstitious themselves through the working of racial psychic momentum."

This childishness has constantly to be dealt with by the physician and the public health worker. "It expresses itself even to those highly educated people who walk about with an iron ring around a finger or a raw potato in their pocket to ward off rheumatism, or who believe that a piece of red flannel has much more efficacy than a white one tied round the neck for sore throat." "One expression of childishness in adult life which may actually be a serious menace to the welfare of the community is the activities of the antivaccinators. This particular form of childishness is that these people are unable to appreciate the import of the historical and statistical evidence in favor of vaccination against smallpox. The antivaccinators do not believe that the question whether there shall or shall not be universal vaccination is one for the medical expert, and not for the layman at all. These antivaccinating members of the laity are impervious to evidence, and are constantly making mistakes about cause and effect. They are the present day representatives of that class of persons who throughout the ages have opposed everything new. Edward Jenner was by no means the only promulgator of a discovery who suffered opposition and misrepresentation, for Galileo, Harvey, Simpson, Semmelweiss and Lister were all, at first, at least, ridiculed, thwarted, and opposed. This form of childishness, as an expression of social psychological inertia, may be a very serious thing for the public health. Possibly some of the leaders of antivaccination are neducable, which is an expression of physiological nertia."

THE RENAISSANCE OF VITALISM

In a most comprehensive article F. Poncetton (*Revue Universelle*, September 1, 1925) presents an riginal critique of Pasteur's theories which have eached their phase of decrepitude, after having iven wonderful results, and puts forward new views n the domination of the nervous system over cells nd tissues. His remarks on cancer should cause one o meditate and to search for other etiological factors nan the microbe. Our twentieth century science has tained the sanctimonious and silly character of the ineteenth century. That the microbic conception aplied to the majority of diseases is at present far too mple is evident in the minds of many and contemprary research work exclusively devoted to serums nd vaccines has unquestionably paralyzed work in her domains of the highest importance.

Vital influx is at present regarded as much more important than in Pasteur's day; we are only just beginning to catch a glimpse of the as yet immense unexplored field of action of the sympathetic and pneumogastric systems and their ganglia, of the blood, lymph, internal secretions and differentiated tissues. Poncetton points out that the body is to be regarded as a city composed of differentiated cells to which the negative nervous system furnishes their vital force, which penetrates each individual cell and governs with marvellous delicacy the entire human machine. The intricate workings of the body remain a physiological mystery composed, as they are, by an accelerating apparatus—the sympathetic—and an apparatus of restraint—the pneumogastric—with ganglia each with its individual life, alliances and antipathies. Finally, surmounting this vegetative edifice which is necessary for it, although it does not obey it, there is the brain which is in relation with the external world by the organs of the senses, thus allowing the individual to construct that imponderable conception, namely human reason. This dissociation of life has in all times been perceived; it will explain the medicine of tomorrow and it can now be affirmed that the twentieth century will be the period of vegetative physiology. It will be by the study of the antagonistic forces—the sympathetic and pneumogastric, ganglia and organic plexuses—that clinicians of tomorrow will create a logical science of disease. Contemporary medical science has its objectives, but it has no starting points, and this is due to the special scientific fetishism at present holding the medical profession in its grasp.

SOME OF THE NERVOUS AFTEREFFECTS OF INFLUENZA

The nervous aftereffects of influenza are many. Of course, influenza has a marked predilection for the nervous system and is responsible for bringing into activity its latent defects. Dr. Smith Ely Jelliffe has appeared to lean towards this view. Encephalitis lethargica, commonly known as sleeping sickness, and poliomyelitis, commonly known as infantile paralysis, are but manifestations of the action on the nervous system of the germ or germs on whatever the causative factors of influenza may be. Dr. F. W. Crookshank, of London, is the chief protagonist of the theory that encephalitis lethargica and poliomyelitis are owing to influenza and many medical men of repute hold a similar opinion among these being, to some extent at any rate, Tarozzi and Rosenow of the Mayo Clinic.

The synthetic view then is that encephalitis lethargica represents a nervous form of influenza that tends to occur in older and epidemic poliomyelitis a like

form that is more frequent in younger patients. Moreover, this conception affords a basis for a rational plan of treatment which has proved successful in practice. In order properly to grasp the significance of this, Dr. Crookshank refers to an old time theory and practice that unless there was sweating or free diuresis in fever or if the rash did not show in certain fevers it boded ill for the patient. When distillation was suppressed nervous troubles were apt to arise, paralyses, lethargies, deliriums, psychoses, and disturbances of special senses, indeed the whole gamut of the manifestations of encephalitis lethargica and poliomyelitis was displayed. Not only did the sixteenth century doctors believe this, but they founded their practice upon the belief and it appears with success. It seems, therefore, as if, no matter what the particular virus to which the condition is owing or chiefly owing, there is in certain disorders a sort of balance between the vasomotor conditions of the central nervous system, on the one hand, and the skin and mucous membranes and viscera on the other. Dr. Crookshank and his colleagues at two London hospitals have had considerable success in treating these conditions, since the outbreak of influenza in 1918, by the addition of urotropin, salicylate of soda and benzoate of soda to the diuretic mixture. It is no doubt required in the treatment of such nervous disorders that diuresis be free and that the urinary tract be disinfected. Urotropin has a remarkable, selective affinity for the central nervous system, exhibited by its rapid appearance in the spinal cord after administration.

TOXICOMANIA IN ANIMALS

It is a question whether or not man is superior to his socalled inferior brothers. It is true that the present theory admits that human intelligence and that of animals—if they be accorded one—differ, not only in degree, but in essence, hence no comparison is possible between the acts of man and beasts. It might be supposed that man only had vices, but there are typical examples of animals who occasionally know the joys of alcohol, as well as the disadvantages resulting from the ingestion thereof. When man makes a beast of himself he usually has no success, and when an animal imitates man, it derives few advantages.

One recalls the story of the ass, related by Zola in *La Terre*, who would drink a tub full of newly pressed wine and then in its inebriety rolled in ecstasy upon the grass. It is probable that this is an authentic fact.

A competent veterinary surgeon, Dr. Bissange, has contributed a long article on alcoholism in farm animals in which he considers the causes, symptoms and degrees. He considers alcoholism in domestic animals rare, because exceptional circumstances must be present for sufficient doses of alcohol to be ingested to cause alarming symptoms. Horses and dogs are usually more susceptible to the influence of alcohol than cattle, but, speaking generally, the impression produced in animals is far more intense than in man. As to chronic alcoholism, Dr. Bissange has never encountered a case in domestic animals.

Some sailors of the Hudson Bay Company once captured a young white bear, who in its captivity willingly entered into the pleasures and sports of its masters. Among other things the animal was particularly fond of grog and became inebriated with deplorable frequency. Upon a certain occasion a sailor gave the animal an overdose and it instinctively went to bed in the sailor's bunk to recover.

Considering now animals observed in liberty, we know the reputation of vine thrush, which becomes inebriated to the point of losing its reason. But special importance is to be attributed to the studies of Wasman, Powell, Oberthür and Bouvier on ants. In them alcoholism is a factor of disheartening social conditions. It is known that some species of ants give refuge to plant lice who serve them like cattle and furnish their hosts with a kind of fermented honey, and, better still, it would appear that certain other guests—Atameles and Lomechusæ—bring up their families in ants' nests and in order to keep in the good graces of the latter in order to get the fermented honey they secrete, the ants take upon themselves the feeding of this foreign progeniture and, as it is voracious, the ants give them the sexualized royal larvæ to feast upon, so that the perpetuation of the race is very much compromised.

The facts seem to show that a kind of toxicomania exists in ants. Wasman also observed that the ants, after having licked up the fermented honey secreted by the undesirable guests, became so excited that their condition resembled an excess of alcohol or ether in man. They also show that in animals as with humans a certain degree of civilization is necessary for these deplorable collective vices to extend by contagion.

Lockwood Kipling has stated that felines, especially tigers, inhale tobacco smoke with great content and an authentic story is told of a young Japanese macaco belonging to a young Japanese woman (who was both a morphinomane and cocainomane) who developed the habit of snuffing cocaine. He progressively increased his doses of the poison and developed all the symptoms of human amateurs of artificial paradise. Finally his mistress went to a sanitarium for a cure and the monkey accompanied her and, taking a cure as well, he recovered from his cocainomania; to such an extent was his cure complete that he ever afterwards refused to sniff the drug.

THE PHARMACOPŒIA

The United States Pharmacopœia has had its tenth overhauling and with notable results. Nearly two hundred articles have been dropped and something like forty added. We do not know how many articles there were at the beginning of this revision, but we are reminded of the old intelligence test in regard to the frog in the well who climbed up two feet during the day but slid back one foot during the night. He got out all right and it looks as if the medical profession, at its present rate of progress, which, if we know any arithmetic, beats that of the frog, is likely sometime to reach that high but very narrow plane of therapeutics set by Dr. Holmes. We have certainly made good headway since his day.

Some of the things thrown overboard deserve a passing sigh or even a tear. There was a day when arnica was essential to the comfort of not a few, and a poultice of humulus has saved many a patient. Trochischi potassi chloratis is dear in our memory, for they were dispensed, along with other candy, by our druggist, and we bought them by the handful in preference to, or as a change from, peppermint or wintergreen lozenges. We should, of course, have been poisoned and have died, but we were none the worse. Sassafras must descend from "official" life and seek simpler company, though it was ever the best of spring remedies and has cleansed the blood of countless thousands.

Among the additions we are surprised to note our friend of questionable company—spiritus frumenti, but circumstances alter cases. He has entered exclusive circles.

There have been a number of changes of official title. Hypophysis sicca is now to be known as pituitarium, and balsamum tolutanum is to be styled simply tolu. Shall we know them under these brief titles? Serum antitetanicum purificatum becomes antitoxinum tetanicum. Liquor calcis is now liquor calcii hydroxidi and pilulæ catharticum compositæ is become pilulæ hydrargyri chloridi mitis compositæ. Some are less, some more, formidable in their new official regalia, but isn't this language all tomfoolery either way? Why not compound cathartic pill, tetanus antitoxin, lime water, etc., instead of the attempt at display of linguistic learning which we do not possess nor need, though it was possessed and was necessary a hundred or more years ago.

The first effort at improving the medical curriculum should be the abolition of the use of Latin in writing prescriptions, and, while this can be done without altering the dignity of the Pharmacopœia, that Latin bible would probably be then translated into the vernacular. Verily the priest has made more progress than the physician in some ways.

Obituary.

ARTHUR ROBERTSON CUSHNY, M.D., LL.D., F.R.S.

Edinburgh

Dr. A. R. Cushny, professor of materia medica and pharmacology at Edinburgh University, died very suddenly at his home in Edinburgh on February 25th last. He was as well known in this country as in his native land as he had spent a considerable part of his working life here where he also did much of his valuable scientific investigations into pharmacology and therapeutics.

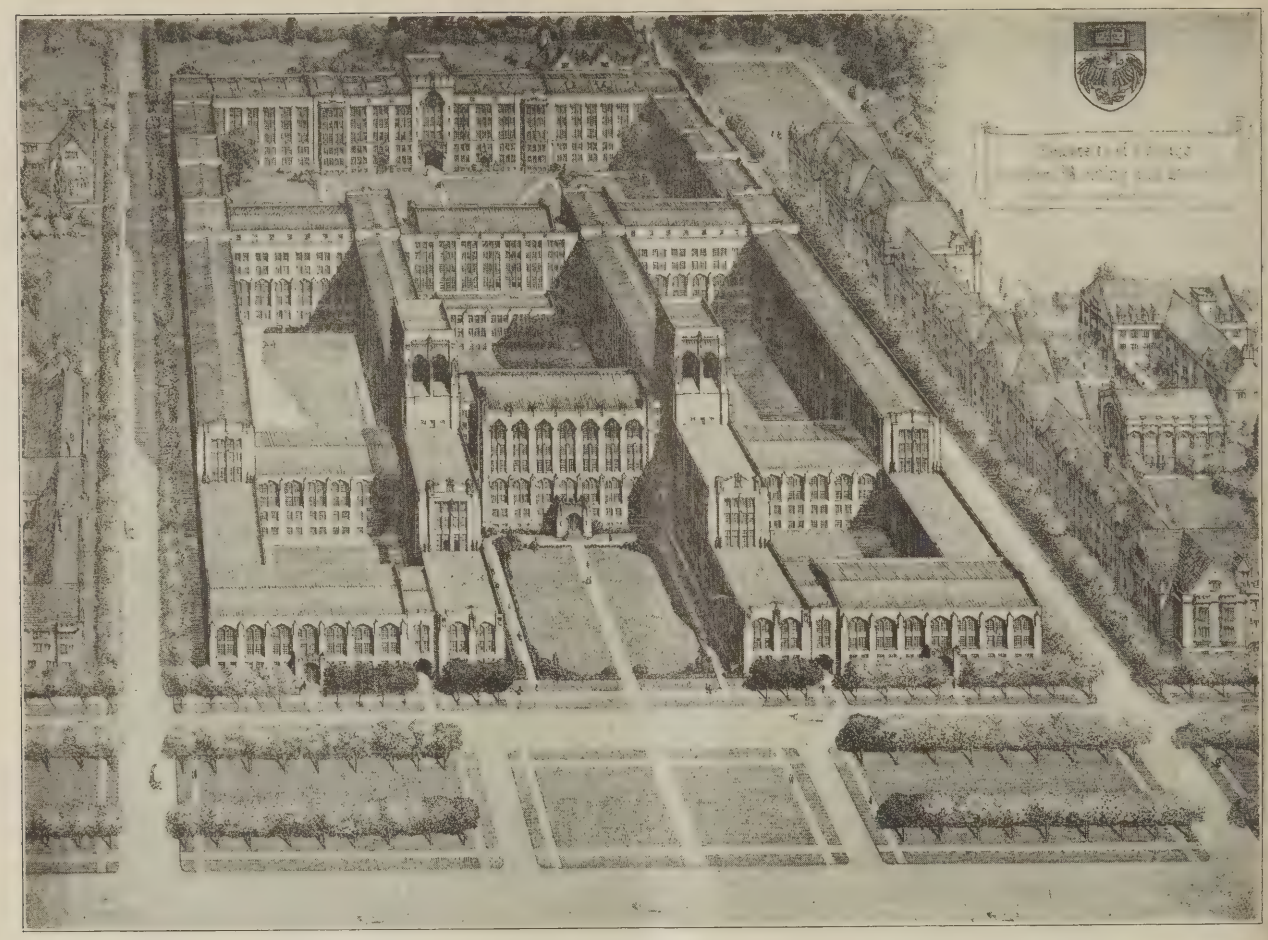
Dr. Cushny was born in 1866, the fourth son of the late Rev. John Cushny, of Speymouth, Morayshire, Scotland. He was educated in Aberdeen where he had a distinguished career as a medical student, graduating in medicine in 1892. He studied also at Berne and Strassburg and in 1898 was elected professor of pharmacology in the University of Michigan at Ann Arbor, which post he held for twelve years when he was appointed to the chair of materia medica and pharmacology in the University of London. He remained in London until 1918 when he succeeded Sir Thomas Fraser as professor of materia medica and pharmacology in the University of Edinburgh.

Among the contributions which Cushny made to the knowledge of pharmacology was the analysis of the mode of action of digitalis upon the heart. He was the first to do this and after establishing the general principles by animal experimentation, in collaboration with his friend, Sir James Mackenzie, carried out a series of clinical investigations and demonstrated the effect of the drug on the heart. This work which was fundamental formed the basis for important researches by Sir Thomas Lewis and others who have cleared up many of the obscure features of heart disease during the past few years. Professor Cushny also did some excellent pioneer work on diuretics and introduced the first coherent theory of the manner in which the kidney acts and which is in accord with the most modern knowledge of physical chemistry.

Dr. Cushny by reason of his life work, exercised a profound influence on the development of pharmacology both in Great Britain and in this country. His great influence was due largely to his textbook, *Pharmacology and Therapeutics and the Action of Drugs,* which was the first comprehensive textbook to be published and which now in its eighth edition still holds the pride of place in this field.

Dr. Cushny's whole influence was directed towards making pharmacology an exact experimental science which would serve as a foundation for the art of therapeutics. He contributed frequently to medical scientific literature and in his later years was joint editor of the *Journal of Pharmacology and Experimental Therapeutics.* His last written work is to be found in a series of lectures given in 1925 under the Charles E. Dohme Memorial Foundation at Johns Hopkins University.

Dr. Cushny was essentially an original worker and a pioneer and established pharmacology on a scientific basis here and in Great Britain. In Edinburgh he built up a great school of pharmacology.



Rush Medical College

An Epitome of American Medical Progress

MAX THOREK, M.D.

Chicago, Illinois

To write of Rush Medical College is to write of Chicago, for the spirit of Rush Medical College is the spirit of Chicago, or, rather, the broader American spirit of liberty and progress. In no American was this spirit more manifest than in the illustrious man whose name this famous college bears. A man preeminent in his profession but even more preeminent in his love of country and one who has left his immortal signature on our Declaration of Independence.

A few words of introduction in regard to Benjamin Rush will not be out of place in speaking of Rush Medical College. Benjamin Rush was born in Philadelphia in 1745. He went to Edinburgh in 1766, obtained his M.D. degree in 1768, then went to Paris and returned to Philadelphia in 1769. He was successively professor of chemistry and of theory and practice of medicine in the Medical College of Philadelphia, and, in 1791, was created professor of the institutes and clinical medicine in the new University of Pennsylvania.

Rush was, however, even more prominent as a patriot. Probably no one outside of Washington was better known and appreciated throughout the country. Among the physicians of his time he stands easily foremost. His character is summed up in Jefferson's letter to John Adams, in which he says: "A better man than Rush could not have left us, more benevolent, more learned, of finer genius or more honest."

Of Rush's many important literary contributions to medicine the best known is his *An Account of the Bilious Remittent Yellow Fever as it Appeared in the City of Philadelphia in the Year 1793.*

No better name than that of one who combined love of independence with the spirit of research could have been chosen for a medical college; and the history of Rush Medical College since its inception is fully in accord with the spirit of its patron. To me, as an alumnus of this college, it is a special pleasure and privilege to furnish this short sketch of its work.

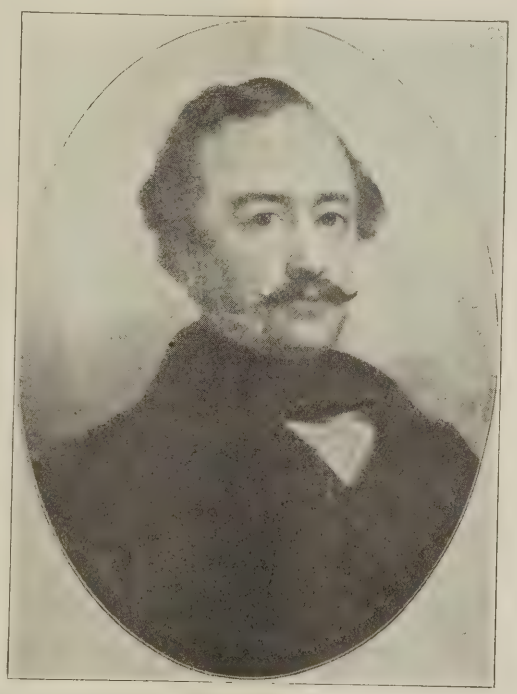
The idea of founding Rush Medical College in Chicago originated with Dr. Daniel Brainard who, not only because of this but for many other reasons, must be regarded as a pioneer in American medical progress and a conspicuous figure in American medicine because of his personal achievements. Brainard was born in New York State in 1812. In 1834 he received

his M.D. degree in the Jefferson Medical College of Philadelphia and settled for practice in the then outlying and distant, but rapidly rising, town of Chicago. In 1836 Brainard, in conjunction with G. C. Goodhue, of Rockford, Illinois, petitioned the Illinois Legislature to grant a charter for a new medical college in Chicago, to be known as Rush Medical College. The charter was granted in 1837, the first educational charter of any kind granted by the Illinois legislature, but owing to financial and other difficulties nothing was done in the way of starting operations until 1843. In that year the first faculty was chosen, and consisted of Brainard himself as president and professor of surgery; Dr. John McLean, professor of the theory and practice of medicine; Dr. M. L. Knapp, professor of obstetrics and diseases of women and children, and Dr. James V. Z. Blaney, professor of chemistry and materia medica. Dr. McLean came from Jackson, Michigan, and Dr. Knapp from Waynesville, Indiana.

The humble beginning of the college was made in two rented rooms in the Saloon Building at the southeast corner of Lake and Clark Streets. The requirements for the degree of M.D., according to the first announcement of 1843, were three years of study with a reputable physician, with two courses of lectures in Rush Medical College, or one course of lectures with two years of practice. Twenty-two students attended the first course of lectures.

The broad, prophetic vision of the founder, however, was in no way dimmed by the smallness of this beginning. His belief in his own ability to build up a great institution, and his clear foresight of the glorious future of Chicago, are reflected in his introductory address in opening the first class, on December 4, 1843, in which he stated that he believed the school opened that day was destined to rank among the permanent institutions of the State, and that it would be identified with the interests of a great and prosperous city. Today, indeed, Brainard's prophecies are more than realized. Without endowments, without patronage, with but little financial or other aid except the indomitable punch and "I will" spirit of its founders and their successors, Rush Medical College has become the nucleus of the medical school of one of the greatest universities of the world, and bright as have been its achievements in the past they may be expected to pale before the dazzling brilliancy of what may reasonably be expected from the future.

With the generosity and public spirit which has always characterized the citizens of Chicago, those of that day purchased a lot at the corner of Dearborn and Indiana Streets, and on this site, in 1844, the first Rush Medical College of Chicago was erected at a cost of about $3,500.



DANIEL BRAINARD

This building was humorously called "the rat trap" by the students. The celebrated Austin Flint gave lectures in this building, as professor of the institutes and practice of medicine, as well as Dr. Nathan S. Davis, who took the chair of physiology and pathology in 1849.

The growing city and the rapidly increasing number of students soon called for increased accommodations, and in 1855 the college was enlarged to a capacity of 250 students, at a cost of $17,000.

The clinical needs of the school were not neglected. Indeed, Dr. Brainard, whose specialty was surgery, had paid particular attention to this branch of the college teaching. Soon after his arrival in the city he opened a private hospital in Rush Street. The old Government Hospital of the Lakes had passed into the hands of the Sisters of Mercy in 1851 and was known as the Mercy Hospital. Both of these furnished clinical material for study by the Rush students.

In 1857 Dr. William Heath Byford, of Evanston, Illinois, became professor of obstetrics and diseases of women in the college. The event is of importance for progress in surgical gynecology is almost peculiarly American, and Byford's name is indelibly associated with much of that progress. The Rush Medical College was naturally a focus for the dissemination of his ideas of the newer gynecology. Dr. Byford, however, with Dr. Davis and others, separated from the Rush Medical College in 1859, to form the medical department of the Lind University, the Chicago Medical College, afterwards to be known as the Northwestern University Medical School. This separation occurred because of a divergence of opinions in regard to the methods of teaching, but in other respects mutually cordial relations have always existed between the two medical schools.

The Civil War affected Rush Medical College only in its clinical teaching. For this material the college had in recent years to depend chiefly upon the City Hospital, which during the war was commandeered by the government as an eye and ear hospital. After the war the hospital passed into the hands of the Cook County authorities and became the nucleus of the present Cook County Hospital.

A most important event to the college was the death of its founder, Dr. Brainard, in 1866. He was the most conspicuous medical figure in the Northwest, an original investigator in bone surgery and the use of iodine in surgery, and had been elected a member of the Surgical Society of Paris, and of the Medical Society of Geneva, Switzerland. Brainard had made the teaching of surgery the most prominent feature in Rush Medical College, a feature which has continued down to the present date. He was succeeded in the chair of surgery by Dr. Moses Gunn, who maintained

and furthered the high standards established by Brainard. As the school progressed, Dr. Charles Parkes became associated with Gunn in the surgical teaching, after fifteen years devoted to the teaching of general and surgical anatomy.

In 1867 an entirely new edifice was erected on the

Rush Medical College in 1876

site of the old college, at a cost of $70,000. This building and its valuable contents were entirely destroyed by the great Chicago fire of 1871, and the college existed only as a legal entity. Chicago, however, has never been daunted by calamity. Three days after the fire classes were resumed and the Rush medical students listened to their lectures in a hall placed at their disposal in the old County Hospital. The Chicago Medical College kindly gave the use of its dissecting room. Because of the out of the way location of the old college in regard to the hospitals, it was decided not immediately to rebuild the college but to await developments regarding the location of the new Cook County Hospital. In the meantime a temporary brick structure, with a tar roof, was built, part of it under the sidewalk, on the grounds of the old hospital. This was the celebrated College under the Sidewalk, or Eighteenth Street Tabernacle. It cost only $4,000 and lasted four years, until the new college was opened. It contained both an amphitheatre and a laboratory.

A site was selected and purchased in 1875 for the new Rush Medical College opposite the newly built Cook County Hospital, at the corner of Harrison and Wood Streets. This site and building cost $75,000, chiefly contributed by the faculty.

The new building was planned to give all necessary accommodations and every improved facility in the teaching of medicine and surgery. Dr. Grossheim, the Surgeon General of the Prussian Army, who visited it, pronounced it the best building for its purpose of any he had examined. Dr. Joseph W. Freer was the president of the college at this time.

A digression might be made here in regard to the surgical clinics in Rush Medical College. The work of both Brainard and Gunn has already been mentioned. Gunn was succeeded in the surgical professorship by Parkes, whose knowledge of anatomy gave great eclat to his surgical demonstrations. But the surgical clinic of Rush attained its zenith during the professorship of Nicholas Senn. Senn had been teaching the principles of surgery in the college from 1888 to 1891, but in the latter year he left his home in Milwaukee to fill the chair of clinical surgery vacated by Parkes. Senn's book, *The Principles of Surgery,* had completely altered the surgical mind of America. Indeed, it is still a standard and no man since Senn's time has left a deeper impression than he created in the surgical practice of the day. Senn was a rapid and accurate diagnostician. As a lecturer he had a wonderful facility for bringing the salient points clearly home to every member of a large audience. His famous clinics in Rush Medical College and elsewhere drew large audiences, many traveling long distances to hear his masterly discourses. In 1905 he became professor of surgery in the University of Chicago.

The other branches of the medical art received all the attention to which they were entitled. I need only refer to the gynecological clinics of Byford, the nose and throat clinics of E. Fletcher Ingals, the dermatological clinics of Hyde and Montgomery, Brophy's clinics on dental anatomy and pathology, besides a number of others, including the more recent night clinic in industrial medicine by Dr. Harry E. Mock, which was established in 1917, to make this fact apparent.

In 1893 an addition to the college was made by the erection of a five story laboratory building in Harrison Street, opposite the college building. Here Dr. Ludvig Hektoen, professor of pathology, gave instruction in gross and microscopic pathology. This was in line with the orientation towards laboratory investigation and diagnosis.

The Sons of Rush Medical College have nobly done their duty in the various wars of the United States. The records of the Civil and Mexican Wars were, unfortunately, destroyed in the great fire. Senn's name and work in connection with the Spanish-American War are well known. In the World War the *Bulletin* of the Alumni Association of the college, August, 1918, shows that about seventy mem-

Rush Medical College before the fire, 1871

bers of Rush Faculty were in active service in the field, and that about seven hundred of the alumni of Rush were enrolled in the Medical Corps of the Army and Navy.

Rush has given its diploma to more than five thousand graduates since its inception. The rolls contain such names as Byford, Fenger, Senn, Cotton, Murphy

and Etheridge among those who have passed on, and a host of distinguished living practitioners who are gloriously carrying out the ideals of their Alma Mater.

We now come to perhaps the most interesting phase in the life history of Rush Medical College, its affiliation with the great University of Chicago. The university was founded in 1891 by John D. Rockefeller and richly endowed, with William Rainey Harper as president. The amalgamation may be considered to have been initiated by Dr. Edward L. Holmes, who succeeded Dr. J. A. Allen in the presidency of Rush Medical College in 1890. Holmes had high ideals regarding practical and laboratory methods in the teaching of medicine. It was mainly through his efforts that students of Rush Medical College obtained their first two years' course, the preclinical course, in the Hull Biological Laboratories of the university, which were fully equipped and sufficiently endowed to provide full time teachers. This arrangement continued for many years, the final degree of Doctor in Medicine, however, being given by Rush Medical College. While Holmes urged the complete affiliation he found it difficult to convince Dr. Harper, whose first idea was that the medical school of the university should be of the graduate research type favored by many of the older European universities. Harper also believed that there might be difficulties in an old established institution, like Rush Medical College, cutting loose from its own traditions and adapting itself to newer ideals in teaching. But gradually Dr. Harper changed his views and the affiliation has been accomplished under his successor, Dr. Harry Pratt Judson.

The affiliation measures and contractural relations call for the establishment of a completely equipped and endowed undergraduate medical school, with a clinical hospital directly in connection with the university, the present Rush Medical College to be replaced by a new and larger edifice, and in connection with the Presbyterian Hospital and others, the Otto T. Sprague Memorial Institute of Infectious Diseases, and certain dispensaries, to form a Post Graduate Medical College and Research Institute, where every encouragement and facility will be afforded for the investigation of medical and surgical research problems and the clinical study of disease.

When the entire project is carried out, and funds for the purpose are now amply available, Chicago will possess what no other city in the United States possesses at present, both a high grade University Medical School and a properly organized and equipped school for the further training of physicians already in the field. What the university aims at is not the graduation of large numbers and turning them loose to swell the already filled ranks of the profession, but rather the better training of those specially selected as being best fitted for the work.

The undergraduate medical school will be situated, with its own hospital, on the south side and will give the full medical course, with the degree. The postgraduate medical school will be situated on the West side and will continue the glorious name of Rush Medical College.

The affiliation means that Chicago will become one of the most important medical centres in the world. Of course, money, energy and will do not make medicine, but there is no reason to suppose that Chicago will lack the brains necessary to make progress, or to attract to her those who have a problem to solve and seek the means of solving it. The World War has shifted the centre of medical and surgical science from Germany to the United States, and Chicago, being the geographical centre of the United States and the headquarters of its most important medical and surgical associations, may logically assume that its medical schools will rank as the most important in the world.

Great and glorious be the future of Rush, and may her light be a beacon unto all the world!

News Items.

Dormitory for Medical Students.—A ten story building for use of students attending medical and dental schools is to be erected in Chicago by the Y. M. C. A. There will be about three hundred and fifty rooms.

Extension Courses at Bad Elster.—Scientific extension courses for physicians will be held in June at Bad Elster, in the Saxon Mountains. The subjects will be general medicine, balneology, and the various cures offered at the institution.

Diabetes Research.—A trust fund of approximately two hundred thousand dollars has been created by the will of the late George S. Cox, of Philadelphia, for a research bureau to seek a cure for diabetes and to advance medical science.

Pyrmont.—The discovery of a new hot spring at Pyrmont, a health resort in Germany, is recently reported. An explosive outbreak caused heavy pieces of iron to be cast forth and huge amounts of boiling water shot up into the air.

Graduate Study in Pittsburgh.—The school of medicine of the University of Pittsburgh announces a two weeks' course for general practitioners, beginning June first, and a third week of laboratory instruction. Diseases of the cardiovascular system will receive special attention.

Harvey Society Lecture.—Dr. B. Brouwer, professor of neurology of the University of Amsterdam, will deliver the seventh Harvey Society lecture at the New York Academy of Medicine, Saturday evening, April 17th. His subject will be Comparative Anatomy and Nerve Pathology.

Medical Exhibit.—There will be a medical exhibit at the coming exposition in Philadelphia, covering all phases of treatment of the sick. A model sanitarium will be shown, and the medical specialties, recent scientific discoveries, pharmacy, dentistry, and the progress of medical education will be represented.

Gift to Northwestern University.—A gift of four million dollars has been received by Northwestern University, Evanston, Illinois, from Mrs. A. Montgomery Ward, for the purpose of providing the highest quality of personnel for instruction and research staff for the medical and dental schools. A gift of similar amount two years ago from Mrs. Ward is being used to build a fourteen story structure for the medical and dental schools. This is to be known as the Montgomery Ward Memorial Medical-Dental Centre.

Meharry Medical College.—This institution, at Nashville, Tennessee, is planning a campaign for an endowment fund, in connection with its fiftieth anniversary, soon to be celebrated. It is now a Class A medical school, and the only one in the south where negroes can obtain a medical education.

Montefiore Hospital Meeting.—The forty-first annual meeting of Montefiore Hospital was held March 28th, at the hospital. An informal reception was held and the buildings and work of the institution were inspected. Dr. David R. Lyman, medical superintendent of the Gaylord Farm Sanitarium gave an address on Sanitarium Ideals.

Gifts and Bequests.—Announcement is made of the following gifts to New York University and Bellevue Hospital Medical College: four thousand dollars from R. T. Crane, Jr., for the study of anaphylaxis; an anonymous gift of ten thousand dollars for expenses in the department of surgery; and an anonymous gift of five thousand dollars for experimental work in ophthalmology.

The sum of fifty thousand dollars has been received by Milwaukee University from Dr. and Mrs. Joseph Schneider, of Milwaukee.

The will of the late Mrs. Emma E. Hewlett of Cold Spring Harbor provides ten thousand dollars for the Huntington, Long Island, Hospital.

Personal.—Dr. Louis Nagorsky of New York has been appointed attending cystoscopist to the Bronx Hospital.

Dr. Everett Dudley Plass has received an appointment as head of the department of gynecology and obstetrics at the college of medicine of Iowa State University; he has been a member of the staff of the Henry Ford Hospital in Detroit.

Dr. George David Stewart of New York has been appointed one of the directors of the Broad Street Hospital.

Dr. Florence L. McKay has resigned as director of the New York State Department of Health's division of maternity and child hygiene, on account of ill health. She will be succeeded by Dr. Elizabeth M. Gardiner, who has been associate director.

Study of Effects of War Gases.—At the request of the American Legion and other agencies, General Frank T. Hines, director of the U. S. Veterans Bureau, upon the recommendation of Dr. Crossman, medical director, has appointed a board of medical officers to conduct an investigation and make an intensive study of the residual effects of warfare gases. The members of this board are: Dr. A. K. Krause, member of the group on investigation and research of the Medical Council of the U. S. Veterans Bureau and associate professor of medicine at Johns Hopkins University. Lt. Col. Harry L. Gilchrist, M.C., U. S. A., chief of research division, Chemical Warfare Service, United States Army; and Dr. Philip B. Matz, Chief, medical research subdivision, United States Veterans Bureau. This board held its first meeting March 9, 1926, at the U. S. Veterans Bureau and it was decided to begin the investigation at once. This will necessitate the study of the present status of some seventy thousand men who were gas casualties during the World War, and will extend over a period of twelve to eighteen months.

Society News and Notes.

At the last meeting of the section on Historical and Cultural Medicine of the New York Academy of Medicine, Dr. Charles L. Dana gave an illustrated talk on Temples of Æsculapius and Therapeutics of Ancient Greece, and Dr. Herman Goodman, an illustrated talk on the History of Phototherapy.

The Physicians' Wives' League of Greater New York will hold its first social event in the form of a luncheon at the Commodore Hotel, April 13th. The object of the newly formed society is spiritual and mental, aid to its members, and financial help to the widows and children of physicians. Mrs. Rose Climenko is president of the society.

* * *

At a recent meeting of the Society of Arts and Letters of Philadelphia Dr. Howard S. Anders spoke on music and health, taking as his thesis "Music is the great preserver of health, for it is one of the finest relaxations for both the audience and the musician, while at the same time it is stimulating and creates vitality in the body."

* * *

The Medical Society of the State of New York held its one hundred and twentieth meeting, at the Waldorf, New York, last week. Between twelve and fifteen hundred physicians attended. One of the subjects considered by the House of Delegates was the medical practice act providing for annual registration of physicians. The committees on public health and on postgraduate instructions made interesting reports.

* * *

The blizzard class, the graduates of the Bellevue Hospital Medical College, who received their diplomas March 12, 1888, the date of the memorable blizzard of that year, will celebrate their thirty-eighth anniversary by a reunion on April 10th. The class will be again the guests of their fellow alumnus, Dr. D. Hunter McAlpin. Dinner will be served at the McAlpin Hotel, April 10th, at seven o'clock. Invitations have been sent out to all the members of the class whose addresses could be procured. Since according to the American Medical Association directory seventy-five are still living of the one hundred and forty-four who graduated at the time, a large attendance is expected. Any one of that class who failed to receive an invitation and desires to attend, should communicate with the acting secretary, Dr. S. Adolphus Knopf, 16 West Ninety-fifth Street, New York City.

* * *

At the annual meeting of the New York Electrotherapeutic Society, just held in New York, the following officers were elected: president, Dr. Harry Eaton Stewart, of New Haven; vice-president, Dr. Richard Kovacs, of New York; secretary, Dr. Charles R. Brooke, of Newark; Dr. J. Willard Travell, of New York.

* * *

The Women's Medical Society of the State of New York held its twentieth annual meeting in connection with the meeting of the State Society. Among the speakers were Dr. Mary J. Kazmierczak of Buf-

falo and Dr. Agnes Brown of Rochester. The following officers were elected: president, Dr. Marion Craig Potter, of Rochester; first vice-president, Dr. M. Louise Hurrell of Rochester; second vice-president, Dr. Adelaide Dutcher of Syracuse; third vice-president, Dr. Edith R. Spaulding of New York; secretary, Dr. Anna Harvey Voorhis of Yonkers; treasurer, Dr. Harriet F. Coffin of New York.

* * *

The National Academy of Sciences has recently announced that it is sponsoring a plan to obtain immediate financial aid for pure science research, to be carried on in the United States, to offset the commercial trend which, they contend, most scientific investigation is taking. The announcement states that Secretary Hoover as chairman of the special board of trustees seeking to obtain this aid, has received expressions of endorsement from thirty university heads in this country.

* * *

Announcement has been made before the French Academy of Medicine of the discovery of an antitoxin against tetanus. The discoverers are Dr. Ramon and Dr. Zoeller who have been carrying on joint investigations for many years. Several hundred persons have been inoculated with small quantities of the virus, and the immunity appeared complete and lasting, and, it is hoped, may be permanent. The new antitoxin will be placed as soon as possible at the disposal of the medical profession.

* * *

A dinner was held on February 25th in the hall of the Royal College of Surgeons, Edinburgh, in celebration of the bicentennary of the Medical Faculty of the University of Edinburgh. The guests included a number of Great Britain's leading physicians and surgeons. There were toasts and responses from representatives of many Scottish and other British institutions and organizations.

* * *

The United Hebrew Charities and the Jewish Social Service Association have been merged, and the latter name retained for the new organization. This change of name reflects the drift from "charity" to social service which has marked the work of the United Hebrew Charities during the half century of its existence.

The Committee on Public Health Relations of the New York Academy of Medicine has recently issued a statement on the menace to health of the recent smoke nuisance in New York, which is well worth quoting. The committee "views with great concern the health hazard which has been created by the late continual, and to a large degree preventable, discharge of dense smoke into the air. On account of the smoke permeating the city atmosphere every one is forced to inhale soot and grit, and at certain levels sulphur compounds, carbon monoxide, and noxious vapors. The pall of smoke hanging over the city is materially reducing the amount of sunlight and is increasing humidity by interfering with evaporation. The interference with the beneficent action of the actinic rays of the sun by the all pervading smoke is detrimental to health, particularly to that of children. The smoke with its impurities greatly aggravates respiratory affections and causes inflammatory conditions of the eyes. It has encouraged and sometimes compelled the closing of windows, thereby interfering with proper ventilation. The Committee on Public Health Relations desires to record its whole hearted approval of the endeavors of the Department of Health to abate this nuisance, which is a discomfort as well as a source of danger to the health of the community, and urges the commissioner to continue his efforts in this direction.

* * *

The Visiting Nurse Association has recently issued its annual report for 1925. This report gives the total number of cases cared for during the year by the nurses of the association as 33,867, a total of 1600 more than in previous years. Of these cases 12,000 were children under six years of age.

* * *

Announcement has been made of a report made recently at a meeting of the Alumni Association of the Massachusetts Institute of Technology by Dr. Charles H. Herty of the finding of a perfect substitute for mercury. Dr. Herty declared that the discovery will stand out as one of the most important of the age. He did not reveal the name of the new substitute, but stated that it is an organic chemical which has been undergoing for several months a series of thorough tests.

* * *

Massachusetts General Hospital.—An appeal for funds is being made by the Massachusetts General Hospital, of Boston. The amount of $3,250,000 is desired, for the construction of additional hospital facilities and the endowment of research and education in medicine and surgery. Plans include additions to the Bulfinch Building, a three hundred bed hospital for patients of moderate means, a new ward building, and extension of the research laboratory, the outpatient and the röntgenology departments.

* * *

Meetings of the New York Academy of Sciences for April at the American Museum of Natural History are those of the section of biology on Monday, April 9th, and of the section of anthropology and psychology on Monday, April 26th.

* * *

At the recent Safety Congress in Albany, called by Motor Vehicle Commissioner Charles A. Harnett, the following motor code was drawn up: Courtesy keeps many a motorist out of a trip to a hospital, court or jail; if another motorist starts an argument, reply with a smile; make frequent inspection of automobile brakes, batteries, headlights, and other equipment; there are still some chauffeurs who have still to learn that gas and booze won't mix; never allow anyone who does not possess a driver's license to run your car; automobile models may come and go, but the back seat driver seems to continue riding; the expert driver is always a careful motorist; of course it is always the other motorist who is the fool—continue driving carefully.

* * *

The New York Microscopical Society will hold meetings at the American Museum of Natural History on Friday, April 9th, and Tuesday, April 20th.

Book Reviews

CHRONIC DISEASES

Chronic Disease. A Working Hypothesis. By E. Bach, M.B., B.S., D.P.H. and C. E. Wheeler, M.D., B.S., B.Sc. New York: Paul B. Hoeber, Inc., 1925. Pp. 142.

This is a book which must be either epochmaking, or of little value. It is a thesis of the authors that the ordinary diet of civilized life predisposes to chronic bacterial infections of the intestinal tract. The cumulative effect of the toxins of these bacteria absorbed daily, year after year, is a potent cause of many varieties of chronic disease. A gram negative bacillus that does not ferment lactose is held to be the chief offender. The patient is rid of his chronic intestinal infection by being placed on a vegetarian diet containing as much uncooked food as possible and is given autogenous vaccines prepared from the feces. By this means Dr. Bach and Dr. Wheeler have been able to cure or relieve patients suffering from eczema, psoriasis, rheumatoid arthritis, epilepsy, Graves's disease, asthma, cancer, as well as a variety of other conditions. The case reports are not always convincing and the reasoning underlying this method of therapy is not always sound. It would be astonishing, but fortunate, if the work of these authors were confirmed.

HYPERTENSION

Arteriosklerose und Hypertonie. Under Berüchsichtigung ihrer Beriehungen zur Gewerbehygiene und Ihrer Bekampfung auf Organotherapeutischem Wege. Von Dr. med. et phil. H. Griesbach. Giessen: Alfred Töpelmann, 1923.

In this pamphlet an attempt is made to demonstrate the value of animasa, a proprietary extract prepared from bloodvessels, in the treatment of hypertension. A brief discussion of the etiology of hypertension is followed by experiments showing the depressor action of animasa on normal animals and men. Then follow protocols of patients with hypertension treated with the drug. Although some falls in pressure are recorded, the results are not convincing, for no allowance is made for the spontaneous variation in blood pressure, and no diastolic pressures are recorded. Further evidence is needed to demonstrate the usefulness of this preparation in the treatment of hypertension.

PANCREAS

Pancréatites Chroniques avec Ictère. Causes, Diagnostic et Traitement. Valeur et Résultats E'loignés de la Cholécystogastrostomie. Par Dr. Pierre Mallet-Guy. Préface de M. le Prof. Berard. Paris: Masson et Cie, 1925. Pp. 265.

In the present monograph Dr. Mallet-Guy treats exhaustively all forms of chronic pancreatitis which are associated with jaundice. The diagnosis is usually made at the operation, when a hard tumor of the head of the pancreas (size of a walnut) compressing the choledochus is found. Whether this tumor is a neoplasm or a benign inflammation of the pancreas is at times very difficult to decide. Usually it is the result of the treatment which ultimately decides this question. Chronic cholecystitis and syphilis are the most frequent causes of this form of chronic pancreatitis. The treatment consists of biliary drainage either by cholecystostomy or cholecystgastrostomy. The examination of the duodenal contents before and after the operation is often of great assistance in arriving at a correct diagnosis. X rays help to decide whether in cholecystgastrostomy the functioning of the gallbladder takes place in a normal way or not. All the topics regarding diagnosis and treatment are described succintly and in a masterly way. The book deserves to find a prominent place in every practitioner's library.

PUERPERAL FEVER

Therapy of Puerperal Fever. By Privatdozent Dr. Robety Koehler. American Edition, Prepared by Hugo Ehrenfest, M.D., F.A.C.S. With Twenty-seven Illustrations. St. Louis: The C. V. Mosby Company, 1925. Pp. 276.

Here is a book that gives exactly what it purports to and does so in a most lucid and concise manner. The many and various types of therapy for puerperal fever, especially those most recently advocated, are carefully and critically considered. In each case the author, after giving the advantages and disadvantages of the method, states his personal opinion of the procedure. This opinion is always conservative and worthy of serious consideration. The author is not carried away by any passing fad in treatment, but views each procedure with broad and open mind. His conclusions are always valuable because of this attitude and also because of his very extensive experience. The style is engaging and makes most easy reading. The case reports are well chosen, always apt, and never excessive in number. The bibliography is most extensive and valuable.

This book presents a well digested and complete survey of the recognized types of therapy of puerperal fever by an experienced physician who is entirely familiar with medical literature and who is most rational and impartial in his judgment.

TROPICAL MEDICINE

Handbuch der Tropenkrankheiten. Herausgegeben von Prof. Dr. Carl Mense, Kassel. Dritte Auflage. Vierter Band, Mit 149 Abbildungen im Text, 18 Schwarzen und 11 Farbigen Tafeln. Leipzig: Verlag von Johann Ambrosius Barth, 1926. Pp. xii-762.

The fourth volume of this encyclopedic work includes the following diseases, discussed by the authors mentioned. P. Manteufel deals with the more important "cosmopolitan" diseases encountered in the tropics, such as typhoid fever and allied diseases, variola and varicella, etc. Dysenteric diseases and similar conditions caused by protozoa are discussed by R. Ruge. The occurrence of nervous and mental diseases is assigned to J. Moreira. Considerable space is devoted to verruga peruviana by H. da Rocha-Lima. The benign febrile diseases of short duration met in different tropical countries, dengue, pappatacci fever, and Weil's disease are taken up by G. Sticker. A large part of the volume is concerned with the amebic diseases of the liver and other viscera in dysentery and is discussed by K. Justi. Kala-azar (visceral Leishmaniasis) is the work of U. N. Brahmachari.

To those practising medicine in tropical regions

this work must undoubtedly prove of great value. To those who have studied tropical diseases in the temperate climates this book will be a revelation, as these diseases often assume different forms in their native habitats. The illustrations are numerous, well executed and many of them beautifully colored. The bibliography in most cases is very exhaustive and authors of all nationalities are given credit.

MEDICAL RESEARCH IN JAPAN

Transactions of the Japanese Pathological Society. Volume XIV. The Fourteenth Annual Scientific Session Held in Osaka, April 4th, 5th and 6th, 1924. Published by the Japanese Pathological Society. Editorial Office: The Pathological Institute of the Imperial University, Tokyo. Pp. xiii-293.

One hundred and seventy-six articles are included in this report, most of them of the nature of short protocols of experimental studies. The subjects discussed are too numerous even to mention and highly technical and the majority of them are of little practical value to the general practitioner. They certainly speak well for the high standards maintained in Japanese pathological laboratories and hospitals. A few of the reports are in the English language, but most of them are in German.

MASSAGE

Massage and Therapeutic Exercise. By Mary McMillan. Second Edition, Reset. With Seventeen Illustrations. Philadelphia and London: W. B. Saunders Company, 1925. Pp. 331.

This book should be read by all surgeons who are interested in how massage and therapeutic exercise can be of distinct help to them in shortening the time of disability of their patients. If the author had not had such medical men as she did have to advise her regarding strictly medical and surgical subjects, one might object to the amount of surgery as such that is included. The reviewer had the greatest possible advantage to observe what rationally directed and applied massage and therapeutic exercise could do during and after the war, and he believes this book can be recommended for reading and study.

PHYSIOLOGY OF REPRODUCTION

Reproduction in the Rabbit. By John Hammond, M.A. (Cantab.) With foreword and chapter on the Formation of the Corpus Luteum by F. H. A. Marshall, F.R.S. (Biological Monographs and Manuals No. IV.) Edinburgh and London: Oliver & Boyd, 1925. 210 pages, illustrated.

In the majority of mammals probably ovulation takes place spontaneously, and whether copulation occurs or not; but in some species, such as the rabbit and the ferret, the Graafian follicles do not rupture and discharge their ova without the stimulus of sexual intercourse. In the rabbit, however, pseudo-pregnancy can be induced under experimental conditions, such as by allowing copulation with a male made sterile by vasectomy; and when this happens, ovulation occurs, succeeded by the formation of corpora lutea, and the consequent growth changes take place in the uterus and mammary glands. Also, in the domestic rabbit, there is no regular oestrous cycle, the animals generally continuing in the state of oestrum for prolonged periods, during which copulation can occur, succeeded by ovulation and pregnancy. It is supposed that, owing to there being no corpus luteum to regulate the time when the follicles ripen, this process can occur at any time under suitable conditions. In this respect the rabbit resembles the domestic fowl, and is quite different from the great majority of animals, so that this study is almost unique in that it is a contribution to an unusual field of animal biology.

The author's full and complete study of the physiology of reproduction in the rabbit is the result of a series of experimental observations covering many years; his work is supplemented by Marshall's valuable chapter on the formation of the corpus luteum. The plates illustrating the book are excellent and numerous.

ELECTRICITY

High Frequency Practice. By Burton Baker Grover, M.D. Fourth Edition. With seventy-three illustrations. Kansas City: The Electron Press, 1925. Pp. 555.

This book on high frequency is more than half composed of directions how to treat about all diseases known to medicine. These treatments are not confined to the use of high frequency alone, but cover the author's idea of how all these diseases can be rather successfully treated with all forms of electricity. The part of the book which deals with the different high frequency currents cannot be classed as authoritative except where direct quotations from known authorities are used. The author forgets frequently that electrical currents always take the shortest possible path (see Fig. 57) and some of his interpretations of the basic actions of high frequency currents cannot be recommended. The book is interesting for reading by those who do high frequency work but cannot be recommended throughout for beginners.

PHYSIOTHERAPY

Physiotherapy. By Harry Eaton Stewart, M.D. With Seventy-eight Illustrations. New York: Paul B. Hoeber, Inc. 1926. Pp. 368.

Dr. Stewart, being one of the younger, modernly trained physicians of vast experience in physiotherapy, has written a volume that particularly shows how useful physiotherapy is as an adjunct to modern medicine and surgery. The whole subject is completely covered in a comprehensive way which should well satisfy the inquiring mind of the physician of today, and it deserves a place with his books on therapeutics.

PHOTOTHERAPY

Ultraviolet Rays in the Treatment and Cure of Disease. By Percy Hall, M.R.C.S. (Eng.), L.R.C.P (Lond.) With Introductions by Sir Henry Gauvain and Leonard E. Hill. With Twenty Illustrations. St. Louis: C. V. Mosby Company, 1924. Pp. 110.

This book on ultraviolet rays is particularly worthy of note. Books have appeared in England for the practitioner and the physicist, but none seems to bridge these fields as well as this volume. The interest in the whole subject of phototherapy is increasing and though not ultraviolet therapy, the author includes some description of the applications of radiant light, making the book rather one on phototherapy with the most consideration given to the invisible rays. The book should prove worthy of reading by all modern physicians.

REMINISCENCES OF AN INVALID

The Idle Hours of a Victorious Invalid. By Lane Crauford. London: Chapman & Hall, Limited. Pp. 245.

This would be a charming book with a trifle less of the pollyanna attitude of sweetness and light. Even so, much of it is delightfully written, and we can forgive anything from a man who has been treated in the course of years of spinal invalidism by fifty-five different doctors! The author states in his preface that he calls himself a "victorious"" invalid because, although many of his doctors tell him he ought to be dead, he is not only alive, but kicking. As a sort of apology that a book of so personal a nature should be written by one not a celebrity, he says, "but everybody is writing reminiscences—stage doorkeepers, butlers and the like—so why shouldn't an invalid?"

The chapters are informal sketches on various phases of an invalid's life and experiences. One is a delightful description of Harley Street, London's "medical" thoroughfare. Another describes with a delicious sense of humor the interior decorations, literary fodder, and other attributes of the doctor's waiting room, in a way which makes the American reader feel that he would be very much at home in such places in London. A third gives us bits of travel and the experiences of a voyage by sea. There is an interesting chapter on Sir Victor Horsley—and so on indefinitely.

Upon finishing the book we feel that this invalid has really been "victorious," and that if he has put perhaps a little too much unctiousness into the telling of his story, it is more because he has assumed a slightly unfortunate literary manner, rather than that it is in the man himself. Doubtless his style arises from his desire to make his book proper reading for invalids or recuperating patients, which, he states, is the real purpose of his work. And in this he has surely succeeded.

PUBLIC HEALTH SERVICE

Annual Report of the Surgeon General of the Public Health Service of the United States for the Fiscal Year 1925. Washington: Government Printing Office, 1925. Pp. 314.

This report shows that the birth rate in the United States for 1924 was slightly higher than that for 1923. In 1924 it was 22.5 births per 1,000 population; in 1923, it was 22.3. The rates varied from 31.6 in North Carolina to 16.1 in Montana. Preliminary figures indicate that the death rate was low. Twenty-nine states had an aggregate death rate of 11.9 per 1,000 in 1924 and 12.4 in 1923. In 1924 in these states the urban death rate was 12.4 per 1,000 and the rural death rate 11.4. An important item in the demographic record for 1924 is the reduction in the number of deaths of infants under one year of age, per 1,000 births, from 77.7 in 1923 to 71.9 in 1924. It will be of interest to quote from the report on two public menaces which have a most timely significance: "While perhaps not strictly within the purview of this bureau, I cannot refrain from inviting attention to the ever increasing number of deaths and injuries from the operation of automobiles. The death rate from this cause has risen from less than one per 100,000 in 1906 to nearly 15 per 100,000 in 1923, or more than 16,000 deaths per year. Incomplete reports for 1924 indicate a still higher rate for that year. For a number of years the physicians of the United States, through the American Medical Association, carried on a publicity campaign against the use of fireworks in celebrating the Fourth of July, with the result that these injuries were reduced to an almost negligible number. As it was thought that warnings would no longer be required, they were discontinued. Reports from thirty-six states of the casualties for the Fourth of July, 1925, show that 111 persons were killed and 1,030 were injured from fireworks as a result of the one day's celebration. Of the injured it is stated that 148 will probably lose the sight of one or both eyes. In many cases injury or death was due to explosives that were considered harmless, such as sparklers, blank cartridges, cap pistols, skyrockets, small firecrackers, and Roman candles. Comment seems unnecessary."

Death rates from diseases of the heart during the last ten years for which data are available show an almost steady increase and indicate that heart disease ranks first as a cause of death in the United States. Influenza and pneumonia combined give rates second to heart disease in magnitude. The death rate from tuberculosis (all forms) in the registration area dropped from 201.9 per 100,000 in 1900 to 93.6 in 1923. Reports from thirty-five states give a death rate of 88.6 for 1924. Deaths from cancer show a marked increase, and those from diabetes mellitus have almost doubled since 1900.

Of outstanding interest and importance were the conference of venereal disease control officers of various state health departments and the U. S. Public Health Service, and also the annual conference of the Public Health Service with state and territorial health officers held in Washington, which was attended by delegates from thirty states and two territories.

The report states that continued difficulty has been experienced in securing candidates who will take the necessary examinations for the regular corps of the Public Health Service. This is due to the shortage of recent medical graduates and to the greater financial returns to physicians in private practice as compared with those in governmental positions.

Medicoliterary Notes.

In Sweden the government controls all radio broadcasting in the country, and it has added to the regular radio programs a series of mental tests consisting of questions similar to the socalled Edison list. After each question is broadcasted, fifteen seconds is allowed for writing the answer. Then the correct answer is given. The audience will also be asked to identify familiar quotations and musical airs. The government radio service is also teaching foreign languages, English being the chosen tongue for this year.

The Department of Physical Education of the School of Education of New York University is giving courses on the special adaptation of physical education activities to subnormal and abnormal cases, according to the *Mental Hygiene Bulletin.* One course gives special attention to the atypical or problem child and to the adaptation of physical education to his developmental needs. This course is intended to fit students for service in an institution or for handling ungraded classes. The New York city school

for the feebleminded at Randall's Island is the laboratory for this course. Three other courses deal with mental patients. The Manhattan State Hospital and the Brooklyn State Hospital are laboratories for these courses.

The cross word craze received a new impetus in Budapest recently when a waiter in one of the biggest coffee houses committed suicide. In his pocket a cross word puzzle was found with the laconic note: "The solution will give you the exact reasons for my suicide and also the names of the persons interested." Police code experts are unable to solve the novel cipher and have called in local cross word puzzle champions.—*New York Times.*

At the recent convention of the New Jersey Mosquito Extermination Association at Atlantic City, it was announced that Dr. William Rudolph Williams of Rutgers University has discovered an effective mosquito repellent to be spread on the face and hands. This is made by mixing ordinary insect powder extract with vaseline, cold cream or face powder, using about fourteen units of the extract to ninety-six units of the cream or powder. This mixture is said to be effective for several hours.

Polygamy has almost entirely disappeared in Turkey, and it is reported that the "new woman" in that land is preparing to plead cases in court, practise medicine, nurse in hospitals, and enter other professions. Numerous organizations devoted to philanthropic, social, intellectual and political interests have been founded by women, and the ladies are even becoming associated, rumor has it, in business with their husbands.

Dr. R. Tait McKenzie, director of physical education at the University of Pennsylvania, is the sculptor of the new memorial that is to be erected in Edinburgh by Scotsmen living in the United States to the regiments of Highlanders who served in the World War, and won from the Germans the title of Ladies from Hell. The site, chosen by the Royal Academy and approved by the Town Council of Edinburgh, is singularly beautiful and appropriate. It is in West Princess Street Gardens, opposite the Castle, at which the central figure of the monument looks up. The memorial will consist of a seated youth in kilts, grasping his rifle which rests on his knees. Behind the figure will be a processional frieze. The lure of pipes and drums is symbolized by the first group of marching figures of a pipe band; next comes discipline in the representation of recruiting officers and files of regulars; determination and enthusiasms are exemplified by the untrained recruits who fall in behind. The central figure of the monument will be bronze mounted on a granite pedestal, and the frieze in white limestone. Dr. McKenzie, the sculptor, served throughout the war as a major in the Royal Army Medical Corps.

Newark's best dressed—or perhaps more truly most dressed man—was certainly discovered recently, when a workman fell twenty feet to the ground and was rushed to St. Michael's Hospital. Orderlies began to undress him, and succeeded in stripping him after twenty-five minutes' labor. He wore the following garments in the order mentioned: a jumper, two sweaters, a coat, another sweater, another coat, a sweater, a suit of heavy underwear, three pairs of trousers, two pairs of socks and a pair of shoes. The account states that he wore only one hat.

A group of Chicago experimenters, Dr. Elizabeth Miller Koch, Dr. R. G. Gustavson, and H. Casan, who represent the cooperative activities of the Department of Pharmacology of the University of Illinois and of the Department of Physiological Chemistry of the University of Chicago, have been able to show probable close relationship between the antirachitic vitamine in cod liver oil and the active constituent in irradiated cholesterol. Cholesterol is a beautifully white crystalline substance of a very complex chemical nature, which, when it is exposed to ultra-violet light or sunlight, is so altered that it may be substituted for the antirachitic vitamine in cod liver oil. The curative properties produced in irradiated foods are supposed to be due to the presence of cholesterol.

Abstracts from Current Literature

GASTROENTEROLOGY

Endoscopy of the Abdomen.—O. E. Nadeau and O. F. Kampmeier (*Surgery, Gynecology and Obstetrics,* September, 1925) recommend the wider use of abdominoscopy in clinical and experimental work on account of its great practical possibilities. It represents the endoscopic method of examining the abdominal cavity and if carefully executed is a relatively simple and safe procedure.

The technic as described consists in producing a preliminary pneumoperitoneum, passing a trocar through the locally anesthetized abdominal wall, and on its withdrawal leaving in place a flexible and airtight sheath. This cannula then permits the introduction of any type of cystoscope preferred by the observer—an instrument either straight or curved, and adapted for either direct or indirect vision. With the cystoscope, an excellent view may be obtained of the interior of the abdomen, particularly in the region of the stomach, liver and bile tracts, and in the pelvic region. The kinds of operative or therapeutic measures performed with the guidance of the cystoscope in the urinary bladder may also be carried out in the abdomen.

In some cases peritoneal adhesions form the chief drawback to the employment of abdominoscopy. The diagnostician using the method must be familiar with cystoscopy, and with the normal and pathological topography of the abdomen.

The Significance of Acute Abdominal Pain.—Richard H. Miller (*Boston Medical and Surgical Journal,* December 24, 1923) says that in any case of acute abdominal pain, a careful history should be taken, and a careful examination must be done. While waiting to arrive at a diagnosis, no cathartic should be given, though enemas are permissible. Morphine must be used with the greatest care because it tends to mask the symptoms and not only render the diagnosis more difficult, but by decreasing the symptoms lull both the doctor and the patient into a false sense of security. Little or nothing should be given by mouth. The physician, if in doubt, should have a surgical consultation early. After all, of more importance than an accurate diagnosis is the decision as to whether or not the condition is surgical, and an occasional operation which turns out not to have been so urgent is of less damage than a life lost because operation has been too long postponed.

Radiology of the Gallbladder by Graham's Method.—Henry Cohen and R. E. Roberts (*British Medical Journal,* July 11, 1925) used the sodium salt of tetrabromphenolphthalein in their studies of ten pathological gallbladders. Their technic is the following:

All cases are first examined radiologically by the ordinary direct method for gallstones. No special preliminary preparation is made except that during the four hours preceding the injection no food or fluid is allowed. Five grams of the salt are dissolved in forty c. c. of distilled water and sterilized by boiling for thirty minutes. This solution is slowly injected intravenously in two doses, half an hour apart. To prevent extravasation of the dye into the surrounding tissues, the needle is inserted separately and blood is allowed to flow before attaching the syringe. The rate of injection should be slow to avoid untoward symptoms. The dye is followed by a few cubic centimetres of sterile normal saline solution to avoid leakage of the salt when withdrawing the needle. During the first day only a glass of milk is allowed for lunch and in the evening. During the second day ordinary fish diet is given. For the forty-eight hours following the injection forty grains of sodium bicarbonate is given every three hours during the day. Two and a half hours after the injection, 0.5 c. c. of pituitrin is given hypodermically, followed threequarters of an hour later by a simple enema. Radiographs of the gallbladder are taken four, eight, twenty-four, and thirty-six hours after the injection. Occasionally unpleasant symptoms of vasomotor shock and a lowering of the blood pressure are observed. Adrenalin may be given to prevent this occurrence. Three physiological requirements must be fulfilled for the gallbladder to produce a shadow: 1, the dye must be excreted by the liver; 2, the dye must be able to pass into the gallbladder; 3, the dye must become concentrated in the gallbladder.

In estimating the value of this method of radiologically examining the gallbladder, three facts must be borne in mind: 1. That only a maximum of thirty-five to forty per cent. of gallstones show evidence of their presence by the ordinary method of direct radiography. 2. That a negative finding by the ordinary method does not exclude the presence of gallstones. 3. That "gallstones are incidental and not essential to a cholecystitis which may necessitate surgery." It is therefore in those cases which by the ordinary method fail to show the presence of gallstones that this method is of particular value. By no other means short of operation can we ascertain whether this negative finding signifies a normal condition of the gallbladder or not. In other words, it should be used as an adjunct rather than as an alternative to the ordinary method of examination.

Acute Pancreatitis.—Andreas Christ (*Schweizerische medizinische Wochenschrift,* June 11, 1925) draws the following conclusions regarding the treatment of acute pancreatitis from his observations on twenty-four cases:

1. In fulminating pancreatitis severe prostration occurs within a few hours. Some of these patients die, whether operated upon sooner or later, regardless of the method used This cannot be determined beforehand, but some patients are saved by an early interference. Therefore, an operation should be done as soon as possible in all severe cases and those showing a stormy course. Drainage of the free exudate, splitting of the serosa of the pancreas, and thorough drainage are indicated.

2. An associated pancreatitis and fatty necrosis occur not rarely in acute inflammation of the calculous gallbladder. In the presence of free exudate the lesser omentum should be incised and the pancreas examined, and after elevating the transverse colon the duodenojejunal fold should be examined for evidence of inflammation. The radical operation (cholecystectomy and possibly choledochotomy) also definitely eliminates the involvement of the pancreas and should be tried under otherwise favorable conditions.

3. Recurrent acute pancreatitis may also occur without cholecystitis and lithiasis and is produced by fermentative process as a result of unsuitable food containing much fat. The repeated attacks eventually require operation, but the autopsy findings may be deceiving, inasmuch as during the attack there is an acute edema, but during the intervals no pathologic changes are found aside from the adhesive pericholecystitis. The specific intolerance toward fat rich food, however, persists and later leads to recurrences. The recurrent acute pancreatitis may precede the severe necrosis, or may recur repeatedly to a lesser or greater extent without danger to life. These attacks were relieved best by absolute fasting and extrastomachic administration of fluids.

Gallstones and Diseases of the Gallbladder.—Among other observations C. H. Mayo (*Annals of Surgery,* May, 1925) calls attention to the following facts: With cholecystitis there are definite reflex symptoms referred to the stomach at fairly definite periods, usually within thirty minutes after eating, with marked qualitative food dyspepsia caused by retention of gas producing, and greasy foods in the stomach constituting so called indigestion with pylorospasm. Less severe pain and more prolonged soreness after spells aid the diagnostician since it is probable that stones are either not present or are too large to obstruct the duct. The tenderness is due to a local peritonitis on an inflamed gallbladder overstretched by spasm of the sphincter of Oddi. With single cholesterol stones, and sometimes with multiple stones, there are few or no symptoms of cholecystitis; those of acute obstruction of the duct by stone occur without reference to meal periods, often in the night, and no soreness or discomfort remains the day after the attack. By palpation at operation the sentinel glands which indicate infection are found to be enlarged in proportion to the nature and amount of infection present. Nature has placed one gland, or two at the most, on each of the ducts, draining a rich lymphatic area. In health they are of a definite size, and in disease they are enlarged.

Cholesterol is increased in blood temporarily by excess of fat in food. There is this excess in pregnancy. Nearly eighty per cent. of the gallbladder diseases now recognized occur in women. Approximately eighty per cent. of these

have borne children, and had the first attack at the period of pregnancy or soon after childbirth. The primary disease is undoubtedly metabolic and involves the liver as well, and may all be of a temporary nature. The secondary disease, formerly called gallstones, is in the gallbladder or is induced by some affection of it. The gallbladder should be removed to eradicate the disease, unless there are such complications as acuteness of attack, the seriousness of the illness, acute pancreatitis, and other organic disturbances. If the gallbladder looks normal and contains a single pure cholesterin stone, or if the patients are of advanced age, cholecystostomy with drainage may be substituted. It is not as effective as cholecystectomy, as it does not relax the sphincter of Oddi.

The conditions of the pancreas should always be recorded at the time of operation, as pancreatic inflammation is usually secondary to disease of the liver, gallbladder and bile ducts. It may recur months after operation, with pancreatic colic and pain in the back, not unlike the original attack.

Gallbladder Disease.—R. S. Fowler (*American Journal of Surgery,* July, 1925) advises cholecystostomy in severe, acute inflammation; cholecystectomy in mild acute and chronic inflammation. Particularly is the latter true when a cholecystectomy can be done in the early stages of the disease. In discussing the relative merits of cholecystostomy and cholecystectomy there are two main questions to be considered, the function of the gallbladder and the final condition of the patient. The first, that of function, can be practically disposed of by the observation that whatever the function the fact is that the body does very well without it. The second, that of end results, is not so easily answered. The final result is dependent on the pathological conditions present and the extent to which it has been removed or relieved by operation.

Statistical results obtained in answer to five hundred and forty-four questionnaires sent out by the author show by their end results that cholecystectomy should be the method of choice.

Gastric and Duodenal Ulcer.—F. B. Mowbray (*Canadian Medical Association Journal,* October, 1925) emphasizes the point that operation is not the conclusion of treatment and should be regarded as the first stage only. During the next six months the patient should be under observation and eat appropriate and easily digested food; lead a regular easy life and refrain from overwork. Medical treatment is of the greatest value as a supplement to surgery, but not as a substitute for it. The success or failure of operation depends very largely upon the way the patient is treated during this period following the operation. We must also remember that though we may cure a peptic ulcer by surgery; when cured that patient may still be liable to attacks of indigestion, as would any normal individual. If as a result of indiscretions of diet, overwork, or for any other cause, he occasionally has attacks of indigestion, let us not assume that the ulcer has returned or that operation has been a failure.

Surgical Treatment of Gastric and Duodenal Ulcers with Special Consideration of Permanent Results.—Hans Finsterer (*Klinische Wochenshrift,* October 15, 1925) states that it has not yet been proved that the term "surgically incurable" ulcer has any justification at all; at any rate it has up to the present time caused much harm, inasmuch as patients, who have undergone several operations, are warned against a truly radical operation on the ground that nothing would be of any help and that the patient is incurable. It is the very cases, in which after three to five operations a really radical operation could eventually secure permanent cures, that show how careful one must be with the use of the term "surgically incurable" ulcer.

The indication for surgical treatment of a chronic ulcer will always remain a subjective one. An internist, who has observed not only good immediate results with surgical treatment, but has also seen good permanent results, will naturally advise a patient to be operated upon much sooner than one in whose experience there were only fatalities and failures. Even in the operation of choice there will be no uniformity for a long time, as even in this respect personal experiences play the most important part.

The author's point of view as regards the treatment of ulcer may be summarized as follows:

In gastric ulcer, a resection is absolutely necessary, not only because of better permanent results, but also because of the relative frequency of malignant degeneration and the impossibility of recognizing this during the operation.

In duodenal ulcer, the resection of the ulcer together with the pylorus and two thirds of the stomach remains the operation of choice. In ulcer that cannot be resected because of anatomic dissemination, the resection is done for the purposes of exclusion, and at least two thirds of the stomach is also removed. Gastroenterostomy deserves consideration under such conditions at the most in old people.

The important question, whether the lesser resections with direct union of the stomach and duodenum give better permanent results than the more extensive resections with anastomosis according to the modified Billroth II method, can only be decided by long periods of observation.

Gastrojejunal Ulcer.—A. J. Walton (*Lancet,* October 17, 1925) arrives at the following conclusions regarding gastrojejunal ulcer:

1. Gastrojejunal ulcer is a relatively rare complication of gastric and duodenal ulcer occurring in a little over two per cent.
2. Its frequency does not warrant the introduction of extensive operations for the treatment of the primary condition.
3. It is almost entirely limited to pyloric and duodenal ulcers.
4. It occurs almost wholly in the male sex, and is found in those cases in which the gastric acidity is high.
5. As a general rule it is found when the acidity after the primary gastroenterostomy persists, this being possibly due to an anatomical variation in the distribution of the oxyntic cells in the stomach.
6. The symptoms of this complication, although slight at first, nearly always commence immediately after the primary operation.
7. The frequency of the condition will probably be diminished by performing the anastomosis rather higher up than usual.
8. The treatment of the established condition should be by partial gastrectomy, which will be aided by placing the stoma rather more remote from the flexure than is usual at the first operation.

Pyelitis Manifesting Acute Abdominal Symptoms.—W. A. Lincoln (*Canadian Medical Association Journal,* November, 1925) says that pyelitis must be suspected in any unexplainable, febrile condition in children, and must always be excluded in acute abdominal conditions, especially appendicitis. It must be kept in mind that appendicitis and pyelitis may occur simultaneously. The early diagnosis of pyelitis may be difficult, because at first there may be no urinary symptoms, or pus in the urine. A careful history, palpation of the kidney region, and even a cystoscopic examination may be necessary to establish the diagnosis.

Appendicitis and Transposition of Viscera.—B. C. Willis (*Annals of Surgery,* August, 1925) presents a case which leads him to conclude that patients with leftsided symptoms and clinical findings suggestive of appendicitis should be carefully examined for transposition of the viscera. In cases of appendicitis and transposition of the viscera the incision should be made to the left of the umbilicus.

The Uses of Celioscopy.—A. Rendle Short (*British Medical Journal,* August 8, 1925) believes that there are a number of cases, not many perhaps, in which celioscopy is a far less formidable alternative than laparotomy. The abdomen may be distended with air without serious discomfort under a local anesthetic through a tiny incision so as to make inspection of the viscera with a cystoscope possible. No harm has been seen to follow this procedure during a year. The advantages of celioscopy over exploratory laparotomy are: 1, absence of discomfort under novocain; 2, the incision is so small as to necessitate a stay in bed of only a day or two; 3, no special instruments are needed; 4, it can be done at the patient's own house; 5, it is available when it would be dangerous to perform laparotomy.

The following lesions have been observed in this way: small malignant nodules on the surface of the liver; the absence of tubercles in a case of suspected tuberculous peritonitis; the extent of a carcinoma on the surface of the stomach; swellings of uncertain origin in the abdomen; the appendix; pelvic tumors; the presence or absence of blood in cases of ruptured ectopic gestation or traumatic rupture of a viscus; "hobnail" liver. Celioscopy does not and cannot replace exploratory laparotomy, where the cause of the condition has to be sought for and does not lie on the surface

of the abdominal viscera; it is principally valuable for what is definitely seen, and not for what is apparently absent.

The technic is simple. Under novocaine anesthesia, or under ether, if preferred, an incision half an inch long is made in the skin and fascia, usually in the midline just below the umbilicus. The incision is made in layer after layer just large enough to admit the cystoscope. The abdomen is inflated with air through the cystoscope, the air being filtered through sterile wool. Observations are then made and when the examination is complete the air is let out as completely as possible and a stitch put in.

Serious Complications Five Months After an Abdominal Contusion.—Perrier (*Paris médical,* December 5, 1925) refers to the case of a man aged forty-one years in whom evidences of intestinal obstruction appeared five months after an automobile accident. Operation revealed a complex mass consisting of omentum and loops of small intestine. It was found that the bowel was being strangulated by a ring of omentum. The affected portion of intestine was resected and an end to end anastomosis carried out. The patient recovered in spite of lung complications. Histological examination of the mass showed that the tissue compressing the bowel consisted of fibrous tissue with disseminated areas of granulation tissue and minute abscesses. The abdominal contusion is believed to have brought about a crushing of the small bowel and tearing of its musculature, followed by retraction of the omentum, stenosis and later strangulation. Stress is laid on the considerable interval of time which elapsed between the accident and the clinical disturbance.

Closure of the Peritoneum Without Drainage in Suppurative Peritonitis.—Billet (*Paris médical,* December 5, 1925), having seen this method used by Ombrédanne in three children with peritonitis of appendiceal origin, of whom two recovered, tried it himself, after much hesitation, and found reason to continue the practice. Of thirty cases of peritonitis, almost all of appendiceal origin, in which he closed the peritoneum without drainage, not one died. The procedure is indicated only if the appendix has been removed. The author does not bury the stump of the appendix. Douglas' cul-de-sac is painstakingly dried and the peritoneum washed with ether. In gangrenous appendicitis the same procedure is followed; in addition, bouillon vaccine is applied to the area of suppuration and antigangrenous vaccine injected subcutaneously.

Rest and Breathing Exercises in the Treatment of Obesity.—G. Leven (*Presse médicale,* December 16, 1925) protests against the assumption that obesity is a mere matter of excess in calories. Obesity is a symptom, not a disease. All recently acquired data on toxic obesity, obesity of endocrine origin, infectious obesity and obesity with brain lesions point to the complexity of the problem. Attempts at simplifying the matter by stressing caloric intake and output lead us away from the truth. In some cases of obesity physical exercise completely fails to reduce weight, while rest in bed for a few days followed by less complete rest causes a rapid drop in weight. However, complete rest is no more the sole therapeutic measure in obesity than is excessive physical exercise. With it should be coupled diet and breathing exercises. While diet alone can reduce some cases, in a larger number the nervous system is the main factor in reduction. There appears to exist a nervous centre which regulates the destruction of fats and is concerned in the production of obesity. The author has reduced some cases by correcting dyspepsia, without changing the caloric intake. The cause of the dyspepsia was sometimes a remote one viz., sexual excesses, mental strain or worry, or physical overwork. Without the regulating centre it would be difficult to explain the cases of increased weight in spite of restriction to very low caloric values; the author has seen and reported such cases. It would also be difficult to account for the well known cases of partial obesity, symmetrical lipomatosis and traumatic obesity. The cases of pronounced obesity are those which benefit the most from rest treatment. In the breathing exercises, after a short preliminary inspiration through the nose, the patient executes a prolonged expiration, as if he were blowing at a candle to bend the flame over without putting it out. The arms are not used in the exercise, which may be carried out when the patient is either standing, seated, lying down or walking. A sufficient expiration is followed by an automatic, abrupt intake of air. Five expirations are carried out in succession, fifteen to twenty times a day, at half hourly intervals. Roger and Binet have shown the rôle of the lungs in fat destruction, but the breathing exercises probably react on all organs and functions of the body, directly or indirectly.

Cancer and Diet.—M. Hindhede (*Acta medica Scandinavica,* October 24, 1925), surveying the cancer situation and noting the increased frequency of cancer for the last fifty years, is confronted with the dismal fact that his own country, Denmark, takes the lead in this regard. Thus in 1900 the death rate from cancer in Danish towns was 120 per 100,000 inhabitants, while in 1915 and 1916 it was 151. About this time London chronicled 112, Paris 111, New York 77 and Calcutta 12 per 100,000 inhabitants. In Denmark seventeen per cent. of all persons that have completed their forty-fifth year have every prospect of dying from cancer. And these sinister findings the author associates with the fact that the Danes are the "best fed people in the world." The Japanese also have a high cancer incidence and their food is rich and highly spiced. In contrast to this is noted the comparative rarity of cancer among uncivilized people who live frugally. And in support of the theory that overfeeding and a diet rich in animal protein plays a rôle in the causation of cancer the author quotes facts and figures. He affirms—indeed demonstrates—that a change from a rich dietary to a more abstemious mode of living is directly reflected in the statistical curve of cancer morbidity. Thus as a result of wartime rationing and also a widespread movement in Denmark, during the last decade, to return to the simple life, there appears a recession or a down-turn in the cancer curve that had ascended steadily for forty years. In other words we have the picture of an unprecedented cancer death-rate among a people regarded as unusually well fed, and concomitant with the leaner years of the last decade, there is recorded a diminution in the cancer death rate, the first in four decades. From his observations the author draws the following conclusions as to the probability of the main causes of cancer:

1. Irritation of the digestive tube (by strongly spiced nutrients, alcoholic drinks, tobacco, etc.)
2. Overnourishment by too varied, too savoury food.
3. A food too rich in animal protein.

To escape cancer we must return to the more frugal habits of our ancestors.

THERAPY

Treatment of Congenital Syphilis.—Carl Stamm (*Monatsschrift für Kinderheilkunde,* October, 1925) treated thirty-nine cases of congenital syphilis with mercury alone and in combination with neosalvarsan, and with bismuth alone and in combination with neosalvarsan, and found that the results with bismuth were markedly better than with the other methods. The preparation used was spirobismol, which contains iodine and quinine in addition to bismuth. The mortality with spirobismol alone was half that when neosalvarsan was used in combination. These favorable results are explained as being due to the fact that bismuth produces a slower destruction of the spirochetes and therefore does not produce a sudden toxic effect through destruction of the spirochetes.

The treatment consists of intramuscular injections only, giving 0.2 to 0.5 c.c. (equivalent to 0.006 to 0.015 gm. of bismuth) twice a week in newborn children and infants. The course consists of ten injections. All the symptoms disappear. The Wassermann reaction may remain positive till after the completion of the first course, but becomes negative after three months. A repetition of the course of treatment is nevertheless necessary.

Therapeutic Properties of Stovarsol.—C. Levaditi (*Lancet,* September 19, 1925) states that stovarsol (acetylaminophenylarsinic acid, 190) has been found to give favorable results in syphilis, yaws, intestinal parasitoses, amebiasis, lambliasis, and in malaria.

Eighty syphilitic patients were treated by ingestion of stovarsol in the form of tablets containing 0.25 gm. Four tablets, representing a dose of one gm., were given every morning in a little water before breakfast in periods of from five to seven days, each period being followed by an interval of equal length. In this way a total dose of twelve to sixteen gm. of stovarsol was given the first month. This method of administration was decided upon with two main ideas in view: 1, better arsenical impregnation, and, 2, prevention of accumulation.

Stovarsol exerts, in a great number of cases, a remarkable action on the primary, secondary, and tertiary erosive

and ulcerous lesions, an action which is often as rapid as that of the arsenobenzenes given intravenously. The product induces a rapid healing of the superficial syphilitic lesions; it is capable of arresting the evolution of the disease and of exerting a favorable effect on the blood reaction. To this must be added the excellent tonic effect which the compound exerts on the general condition of the patients. To prevent the occurrence of arsenoresistance and relapses, bismuth may have to be used in addition. The indications are hypersensitiveness to salvarsan, difficulty of giving intravenous injections, impossibility of applications other than per os, replacing salvarsan in its association with mercury or bismuth.

The efficacy of the method, its exceeding simplicity, and the security which it gives in a multitude of circumstances render it worthy of further trial.

Clinical and Pharmacological Studies on Peristaltin "Ciba": Its Effects and Indications for Intravenous Use. R. Wolfer (*Schweizerische medizinische Wochenschrift,* August 13, 1925) found that the intravenous administration of peristaltin in therapeutic doses is harmless, especially in regard to the circulation and the kidneys. Its action is that of an active cathartic and regulator of the intestinal activity without colicky pains and vomiting. The peristaltin acts intravenously as a glucoside complex without the splitting off of free anthrachinones. It affects the entire gastrointestinal tract and probably is the result of stimulation of Auerbach's plexus without any action upon the nerve fibres going to the muscles. Special attention is called to the effect of the increased tonus and peristaltic activity upon the small intestine in the cat and the stomach in man.

The main indications for the intravenous use of peristaltin therapy are the following: peritonitis and postoperative paralysis of the intestine; spastic and paralytic ileus; chronic obstipation; atony of the stomach; and conditions that demand a rapid epthying of the intestine (poisonings, gastrointestinal intoxications, etc.). The dose can without harm be increased up to two ampules. Subsequent injections at short intervals are harmless and often necessary, giving an increased action. Peristaltin may also be used intravenously in infancy.

Treatment of Exophthalmic Goitre.—Felix Klewitz (*Klinische Wochenschrift,* September 3, 1925) discusses some of the therapeutic measures available in the treatment of exophthalmic goitre.

It has been shown that an increased metabolism from hyperthyroidism can be reduced to normal with arsenic. Small doses of Fowler's solution are given.

Iodine therapy is still under much dispute, but fairly good results have been observed with an initial dose of three drops of a five per cent. solution of sodium iodide given three times daily, which dose is gradually increased to twenty drops three times daily.

A purely symptomatic effect is obtained with the nervines, especially the bromides, giving one gm. of potassium bromide in the morning and at noon, and two gm. at night.

Good results are reported from sodium phosphate, possibly given in conjunction with arsenic.

In light cases fairly good results are obtained with antithyroidin therapy, but it fails in the more severe cases.

Of the physical methods, röntgenotherapy has undoubtedly given some good results. In status thymolymphaticus, a preliminary irradiation of the thymus has been recommended. Only the following types of cases are suitable for this form of treatment: 1, the formes fruste; 2, the acute cases with pronounced toxic symptoms, including also the cases with status thymicolymphaticus; 3, cases with cardiac insufficiency or with other complicating diseases, where operation is contraindicated; 4, cases in which operation has been performed with no result, or those in which operation has been refused. The last two groups of cases show less favorable results than the first two, but no other treatment is available. Galvanization does not deserve the neglect that is usually accorded to it.

Other measures that may be of use are hydrotherapy (carbonic acid baths or indifferent warm baths with extract of pine needles). More important is the institution of a suitable dietotherapy with sufficient calories and a proper restriction of animal proteins (especially the articles of food containing tryptophan). The caloric values are increased mainly by the use of fat. Sufficient rest in bed is absolutely necessary. Climatotherapy at moderate altitudes is also worth mentioning. Of drug therapy, digitalis, in combination with quinine, may be tried.

Conservative Treatment of Glaucoma.—The following line of treatment is recommended by J. Burdon-Cooper (*British Medical Journal,* September 19, 1925) in the cases of glaucoma seen in the early stage:

The patient is given a bath at a temperature five degrees above that of the body, so as to relieve the internal congestion by peripheral dilatation of the blood vessels; this is essential. After the bath, the patient is put to bed, given a hypodermic injection of 0.25 grain of morphine, and after this an alkaline mixture containing bicarbonate and citrate of potash and soda, with one minim of liquor trinitri for a dose every three hours. The skin should be encouraged to act either by an electric blanket or hot water bottles. The urine should be tested beforehand. The only contraindication to the continuance of the nitroglycerin is the heart's action. The pulse rate should not be allowed to exceed 90. The hypodermic of morphine should be repeated the last thing at night and kept up twice daily until the attack begins to decline. The continuous application of dry heat to the eye is essential until the eye shows manifest signs of improvement. The author always uses eserine for an acute attack, and preferably the salicylate in 0.5 per cent. solution, which is instilled into the eye every three hours. An aqueous solution is absorbed better than an oily one. As soon as the attack subsides the drops should be changed to pilocarpine, two grains to the ounce, which should be gradually reduced to one grain or even 0.5 grain. Miotics should be used infrequently and as weak as possible, compatible with securing the necessary miosis. Dionine or adrenalin should not be used.

Subconjunctival injections aggravate the pain and should not be used. Injections of the nasal duct with twenty-five per cent. antipyrine and swabbing the nasal mucosa with 50 per cent. cocain over the region of Meckel's ganglian has been advocated for the relief of pain. The pressure massage of Domec is very useful and should be done frequently. Venesection is very useful to combat an acute attack and to relieve ocular tension. In established glaucoma venesection should always be performed.

Perfect rest and quiet are essential and the room should be only partially lighted. The air of the room should be moist. Inhalation of oxygen has been recommended to relieve the heart and improve the deoxygenation of the local and blood supply consequent on the stasis. The diet should be restricted and nonstimulating, and during the height of the attack large quantities of fluid should be prohibited. After the tension has come down the kidneys may be stimulated. The bowels should be emptied. The most useful drugs are: alkalies, iodides, salicylates, sodium bromide, chloral hydrate, strophanthus, and gelsemium.

In avoiding subsequent attacks it is advisable for the patient to lead a quiet life; chills should be avoided and woolen clothing worn next to the skin. Special attention should be given to the kidneys, heart, intestines, nasal sinuses, and the teeth. The climatic treatment is important. High altitude and too bracing and dry a climate is bad.

Treatment in High Altitudes.—J. H. Hirschfeld (*Schweizerische medizinische Wochenschrift,* June 4, 1925) draws the following conclusions:

1. The climate of high altitudes is a curative factor consisting of various distinct influences.

2. The favorable effect of such a climate upon many diseases is due to the diminished oxygen content of mountain air, which remains the same throughout the year at a certain level, and within the same barometric variations. Consequently the results achieved in these diseases at high altitudes are independent of weather, whereas in tuberculosis and similar diseases the sunshine is significant.

3. Gymnastic exercises can be adjusted to the abilities of the individual and thus fatigue may be avoided more easily than with other forms of exercises.

4. Both the gymnastics and the mountain climate have the effect of physical therapy.

5. With the combination of mountain climate and methodically graduated gymnastics, the functional ability of both the entire body and of individual muscle groups and organs can be improved more easily than with either factor alone.

6. The mountain climate alone, and especially with the addition of gymnastics, is the most effective remedy to relieve the patient of the functional disturbances of health. In all bodily ailments of a psychoneurotic nature, more rapid and better results are achieved with this treatment in high altitudes than in the lowlands.

GENITOURINARY DISORDERS

Tumors of the Testicle.—F. G. Bell (*British Journal of Surgery,* July, 1925) avers that:

1. The majority of testicular tumors belong to the teratoid category.
2. The relative representation of the various blastodermic derivatives varies greatly in different specimens.
3. Overgrowth of one blastodermic element with partial or total suppression of the others occurs frequently. Hypoblastic overgrowth is most common, mesoblastic next in frequency, and epiblastic least common.
4. Such overgrowth may be simple or malignant, and produces many variations from the typical three layered teratoma.
5. Teratoma testis is potentially malignant to a high degree.
6. Many carcinomata of the testis can be directly related to the malignant conversion and overgrowth of the epithelial, more especially the hypoblastic, elements of teratomata.
7. The malignant change may be selective, but may affect both epithelial and connective tissue elements in the same tumor.
8. The more adult the structure of the teratoma, the less liable is it to malignant change and conversely.

The fact that the bulk of the testis proper is usually situated towards the upper pole in teratoid tumors suggests that, in early cases at any rate, some diagnostic use might be made of it. Testicular sensation limited to the upper pole might occasionally give a clue to the nature of a particular tumor.

In cases coming under observation early, it would appear possible, from a study of the cut surface of the smaller tumors, to enucleate the teratoma from its capsule, leaving the testis and epididymis intact. However, in a paired organ like the testis such conservatism would rarely be indicated.

The use of the x rays may occasionally give additional information in a dubious scrotal tumor if the cartilaginous elements are well developed, and especially if bone is a prominent feature, as in the teratomatous (dermoid) cyst.

Ureteral Repair and Transplantation.—C. H. Mayo (*Annals of Surgery,* September, 1925) declares himself opposed to any method of developing a new bladder sac by using the mucous membrane, skin flaps, or skin grafting. Nor does he recommend any form of closed intestinal pouch as an artificial bladder, but offers the Coffey technic with slight modifications, as follows:

The intraperitoneal operation should be performed on the right ureter first, as the sigmoid is more difficult to handle on the right side after being fixed by an anastomosis on the left side. The incisions are oblique abdominal. The ureter can be seen attached to the back wall of the pelvic peritoneum. Its situation can be determined by the wave of peristalsis in it when the point of a forceps is drawn across its covering layer of peritoneum. The peritoneum is opened and the ureter separated down to a point from 2.5 to 4 cm. above the bladder. The ureter is divided and held in forceps and the lower end ligated. The peritoneum is then closed by suture, just leaving the ureter loose as it passes through the opening in it. A needle with No. 2 chromic catgut is now passed 0.6 cm. up the lumen of the obliquely cut end of the ureter, out through its wall, and then passed in again 0.3 cm. further on. It is then carried down the lumen of the ureter again and out at the open end. Two knots are tied and the short end of catgut 6.25 cm. long, is not cut but is passed into the lumen upwards its full length. This is a most important recent development in technic. The long end is left hanging for future use. The bowel is now cut longitudinally, in line with, or down, the centre of a longitudinal muscle band 3.75 cm. long. This cut does not open the mucous membrane. The sharp edge of the knife is pushed against each side of the cut muscle and peritoneum, separating the cut edges 0.90 cm. With a sharp small pointed knife a puncture of the same size as the ureter is made in the mucous membrane at the lower end of the incision in the bowel. The outer flap of the incised bowel is trimmed at the upper end to just the depth of its dissection in order to make room for the ureter to lie in the trough against the mucous membrane without being pinched at this point. The ureter is stripped and loosened for 6.25 cm. It may become kinked and fail to deliver urine for two or three days through a half paralyzed lower end of ureter. The curved needle with the thread of chromic gut that was left hanging from the lumen of the ureter is now passed into the lumen of bowel by way of the puncture described and out through the bowel wall 1.5 cm. below the opening; the thread drawn tight draws the ureter into the bowel.

A needle bite is now taken in the wall of the bowel and the thread tied to fix the end of ureter within the bowel at this point. In suturing the dissected flaps, every other stitch catches the outer tissue of the ureter to fix it. The peritoneum is now closed over the ureter by interrupted sutures. A running suture is employed to cover these sutures as well as the fixing suture which holds the end of the ureter in place.

The mortality is low for the apparent seriousness of the operative procedure, being by 13.33 per cent. in the sixty patients operated on. Operation is justified by the relief which follows it.

Movable Kidney.—C. P. Mathé (*Surgery, Gynecology and Obstetrics,* May, 1925) finds that the great majority of movable kidneys cause no symptoms and require no treatment. In a certain percentage of cases, however, renal mobility forms a definite clinical entity characterized by lumbar pain, urinary, gastrointestinal, and nervous disturbances, loss of weight, etc., and require fixation by abdominal support or surgical intervention.

The condition is more common in the female because the renal fossas are shallower, cylindrical or even funnel shaped, being wider below than above. This predisposition to displacement is increased at puberty because of the widening of the bony pelvis. In males the renal fossas are pear shaped, being narrowed below. Its greater frequency on the right side is due to the shape of the renal fossa, the presence of the liver on that side, and the weaker support afforded by the less well developed right perirenal fascia.

The majority of cases of renal ptosis can be relieved by the proper abdominal support, fattening, and strengthening exercises.

Nephropexy is a justifiable operation. It has been employed by numerous urologists of note who have found it satisfactory. It relieves symptoms and is indicated in the following cases of movable kidney: when the belt fails or is poorly tolerated; in those cases complicated by ureteral kink caused by fibrous bands; when the sag of the kidney has caused the ureter to kink over an aberrant vessel; in those cases in which adhesions have developed around a prolapsed kidney holding it in place; chronic colon pyelitis when faulty drainage due to increased mobility is not corrected by the belt.

Renal Papillomata and Ureteral Implants.—D. Bissell (*Surgery, Gynecology and Obstetrics,* March, 1925) concludes that implants occur from above downward or in the direction of the urine stream and never from below upward unless by continuity; therefore the urinary tract below the primary growth is peculiarly subject to this form of metastasis.

That when renal papillomata occur, the ureter of the affected side seems more susceptible to secondary involvement than does the bladder, and is usually affected prior to it.

That implants may occur anywhere along the ureter but are more liable to occur when there is a retarded flow as at the vesical orifice, or at points of injury, as when the ureter is severed and tied on partial removal.

That we are not justified in concluding, when nephrectomy is contemplated for renal papillomata, that the ureter is in its entirety normal because its vesical orifice seems not involved.

That as the ureter is susceptible to implants from the moment the primary growth above begins to throw off particles of itself, it should be considered a harbinger of danger, and as the ureter, under these circumstances, is a probable pathological entity, it is advisable to remove it *in toto.*

That if the ureter is not completely removed at the time of nephrectomy, its remaining portion should be removed as soon after as the patient's condition permits.

That the best method of removing completely the remaining portion of the ureter is by the combined transperitoneal and transvesical route.

Torsion of the Spermatic Cord.—M. Thorek (*Annals of Surgery,* June, 1925) declares that where the testis is fully descended and the torsion is very recent detorsion should be attempted, and may prove efficacious if it can be executed by external manipulation. The torsion is, however, likely to recur, and operation will ultimately have to be done to obtain permanent relief. Meantime partial or complete atrophy of the testicle may occur. After operative detorsion, if the testicle can be saved, an orchidopexy should be done to prevent recurrence. Orchidectomy and epididymectomy is indicated in every case in which necrosis, gangrene, atrophy, or persistent circulatory disturbance is present. Even though atrophy might reasonably be expected, where it has not already occurred, yet the dangers which may arise from possible infection suggest removal of the testicle and tunica vaginalis with shutting off of the peritoneal cavity. When the testis is undescended, if transposition into the scrotum cannot be properly directed, the same rule should apply.

The Mechanism of Epididymitis.—H. C. Rolnick (*Surgery, Gynecology and Obstetrics,* July, 1925) finds that epididymitis secondary to a posterior urethritis or vesiculitis results from extension of the infection along the lumen of the vas deferens, the mechanism here being the regression of the bacteria toward the epididymis following each peristaltic wave toward the posterior urethra.

Although no definite proof has been brought forth, it is most probable that bacteria are blocked in their passage up the epididymis beyond the tail, just as fluids are blocked experimentally, so that the bacteria involve the rest of the epididymis by peritubular extension and not intratubular extension, producing a periepididymitis rather than epididymitis of the body and head.

This may explain in part why it is that a gonorrhœal epididymitis is practically never an epididymoorchitis but a pure epididymitis, the organisms not having traveled up the tubule of the epididymis beyond the tail.

This epididymitis rather than epididymoorchitis may also be accounted for by the resistance of the testicle to the gonococcus. It may also be explained by the fact that the tunica albuginea being of a different structure than the tunica vaginalis arrests the extension of the infection to the testicle.

If our deductions are correct then epididymotomy is an operation that should be limited to the tail of the epididymis, for it is here that the process is intratubular. As performed at present it is more or less of a blind operation, the whole epididymis being slashed in many directions. Incision of the epididymis tubule does not increase the danger of occlusion as has been shown clinically and also experimentally with the vas deferens because the epididymis undoubtedly has an equal regenerative capacity.

Undescended Testicle.—S. G. Sonneland (*Surgery, Gynecology and Obstetrics,* April, 1925) offers a new theory for the explanation of ectopic testis based upon 1, the presence of a chorda gubernaculi which is functionless following the escape of the testis from the subcutaneous inguinal ring; 2, a sufficient length of the spermatic cord to permit the excursion of the testis upon certain well defined fascial planes outside the subcutaneous inguinal ring; 3, the peculiarity and constancy of the distribution of fascial planes over the lower part of the ventral abdominal wall and in the perineum, and 4, the operation of physical laws which govern a moving body. The migration of the testis divides itself naturally into three stages, 1, intraabdominal, 2, intracanalicular, 3, extracanalicular. While other forces aid the normally moving testis in the first two stages, in the extracanalicular area the chorda functions quite alone and is of necessity solely responsible for the movements of the testis through this zone and onward into the testis sac. The essential factor of ectopic testis is thus in all probability a fracture or transverse separation of the chorda gubernaculi in consequence of the excessive stress upon it.

The subsequent fate of the testis as far as its position is concerned depends upon certain further factors, some of which are variable, such as the degree of tautness or laxity of the spermatic cord, the degree of development of the superposed cremasteric muscular loops, and peculiarities of insertion, relationship and continuity of certain fascias (Scarpa's, Colles', Buck's), which are fixed and invariable over the lower part of the ventral abdominal wall and in the perineum.

Thus if the spermatic funiculus is extended and taut at the time the chorda breaks, and more particularly if in addition it is equipped with a well developed cremaster muscle, then the probability that the testis will be retracted into the inguinal canal is great.

In further support of this new accident-gravity interpretation for the occurrence of ectopic testis, the author desires finally to emphasize that there is a physical law to the effect that under gravity a moving body tends always to establish an equilibrium for itself and to come to rest. That there exist several normal fascial recesses or pockets the interiors of which are continuous with the only fascial plane upon which a testis with an inclination to become luxated may move, these pockets thus becoming available to such testes under the influence of gravity, is recognized as is the fact that these fascial recesses are the familiar habitats of the ectopic testis.

It would seem reasonable to conclude therefore that the presence of a testis within the confines of such a fascial pocket is evidence of the successful operation of a law of physics in a definite and favorable environment, and not at all due to the activities of a chorda gubernaculi with multiple distal insertions which cannot be proven to exist.

Malignant Tumors of the Testicle.—F. Hinman, T. E. Gibson and A. A. Kutzman (*Annals of Surgery,* October, 1925) state that a final analysis of their cases show that we have to consider but two types of testicular tumor, both of which are malignant, the teratoma or mixed tumor and the seminoma or unicellular type of tumor. The pathology of testicular tumors would be further simplified if we could accept Ewing's dictum that the seminome is also of teratomatous origin, and represents merely a one sided (monodermal) development of a tumor primarily tridermal in constitution. Although we have not subjected our own specimens to serial section, we have been impressed with the uniformity of seminomata as distinguished from mixed tumors and were likewise skeptical of Ewing's beliefs until studying specimen No. 2356 in our series. We have always subjected our seminomata to careful histologic study in an effort to corroborate Ewing's theory, and were finally able to do so with this single specimen in which mixed tissues of various types were found abundantly associated with typical seminomatous tissue. The term "seminome or "spermatocytoma" must therefore be regarded as a misnomer, and the contention of Chevassu is disproved in favor of Ewing's theory.

Spastic Obstruction to the Ureters.—T. N. Hepburn (*Annals of Surgery,* June, 1925) finds that spasm of the ring muscle bundles described by Brödel is a frequent cause of ureteral obstruction.

The trigone controls both inlets of the bladder by action of the interureteric muscle—each end of which encircles the ureteral openings. Spasm of this muscle can be definitely diagnosed as a cause of ureteral obstruction, and may be successfully treated surgically.

Cutting the interureteric muscle and closing the cut anteroposteriorly in conjunction with dilatation of the intramural portion of the ureters with bougies is the best treatment for those cases that will not yield to hygiene or dilatation with bougies.

Heat Treatment of Male Gonorrhea.—D. A. Brown (*American Journal of Surgery,* August, 1925) says: Because of the recognized value of heat in combating gonorrhea in the male, I have been making use of an irrigating medium of a basic normal saline solution heated to 120° F. In acute cases, I have found that the urethra will tolerate an irrigating solution gradually increased from 110° to 120° F. with no discomfort. The urethra is very gently filled with the irrigating solution after the anterior portion is first washed out; then, when the meatus is compressed the substance is retained for several minutes. At one irrigation 2,000 c.c. of solution are used; the treatment is time-consuming, but the results to date justify the time and care. During the first week the patient is instructed to inject from two to four c.c. of one per cent. mercurochrome four times a day after urinating. The rapid disappearance of gonococci from the discharge leads me to believe that this simple method of employing heat is as effective as any of the more complicated processes. The patient is instructed with regard to general hygiene, rest, diet, the drinking of large quantities of water, sexual and alcoholic abstinence, and alimentary elimination.

Medicolegal Notes.

SOUND HEALTH WITHIN MEANING OF INSURANCE POLICY

The Georgia Court of Appeals holds, National Life and Acc. Ins. Co., 129 S. E. 113, that the term "sound health" as used in a life insurance policy which provides that there shall be no liability thereunder if the insured is not in sound health at the date of the issuance of the policy, is properly defined in a charge to the jury in an action on the policy as follows: "If the insured enjoyed such health and strength as to justify the reasonable belief that she is free from derangement of organic functions, or free from symptoms calculated to cause reasonable apprehension of such derangement, and to ordinary observation and to outward appearance her health is reasonably such that she may with ordinary safety be insured and upon ordinary terms, the requirement of good health is satisfied . . . The term 'sound health,' or 'good health,' used in a policy, means that the applicant has no grave impairment or serious disease, and is free from any ailment that seriously affects the general soundness and healthfulness of the system."

ACTS OF EXAMINING PHYSICIAN AS AGENT OF INSURANCE COMPANY

The Georgia Court of Appeals holds, Mutual Life Ins. Co. v. Brown, 129 S. E. 307, that where a physician has, in behalf of a life insurance company, examined an applicant for insurance whose application has been procured by a soliciting agent of the company, an acceptance of the physician's report with knowledge of this fact and the issuance to the applicant of a policy of insurance based upon the report amount to a ratification of the act of the physician in making the examination for the company, and it follows that the physician in making the examination acts to all intents and purposes as the company's duly authorized agent. It is held not necessary to such ratification that the insurer, through its officers who accepted the report of the physician and issued the policy, should have actual knowledge of all the information given by the applicant to the physician in the course of the examination. Any such information given to the physician is, although not reported to the company's officers whose duty it is to pass upon applications and issue insurance, nevertheless notice to the company.

When the answers made to the physician by the applicant, in response to questions by the physician, are not recorded by the physician, and are not reported by him to the company's officers whose duty it is to pass on applications and issue policies, and although the applicant may have signed the record of his answers made by the physician, and certified that "each and all of the foregoing statements and answers were read by me, and are fully and correctly recorded by the medical examiner," it is held that the company cannot, in an action on the policy, defend on the ground that the applicant withheld certain material information and thereby fraudulently induced the company to issue the policy, notwithstanding a provision in the policy that it and the application constituted an entire contract, and that all statements made by the insured should, in the absence of fraud, be deemed representations and not warranties.

CONSTRUCTION OF TOTAL DISABILITY PROVISION IN INSURANCE POLICY

In an action on a policy providing for full indemnity if the insured, from accidental injury, should be continuously and wholly disabled and prevented from the date of the accident from performing any and every kind of duty pertaining to his occupation, it appeared that the insured, a ship surveyor accidentally fell and was struck upon the head and chin, causing a lesion in the left internal capsule of the brain, resulting in hemiplegia, accompanied by aphasia. He attempted to continue at work and apparently did so until he became paralyzed and was unable to get about at all. The New Jersey Supreme Court held, Booth v. United States Fidelity & Guaranty Co., 130 Atl., 131, that the fact that the insured tried to work was not to be taken as conclusive evidence of his ability to do so, so as to deprive him of the right to full indemnity, and that he should not be penalized for honest efforts to keep going when nature demanded that he desist.

INSUFFICIENT EVIDENCE OF NEGLIGENT TREATMENT IN HOSPITAL

In an action against a physician who owned and managed a hospital for injuries alleged to have been sustained during plaintiff's period of child-birth by negligent bathing with an excessive amount of bichloride of mercury, the Maine Supreme Judicial Court, Mills v. Richardson, 130 Atl. 353, granted a new trial, being of opinion that the jury erred in their finding for plaintiff, because, "especially in the light of the testimony given by medical experts called by both sides, the conditions of which the plaintiff complains were more likely to have arizen from leucorrhea and other physical conditions than from the douche."

EXPERT TESTIMONY AS TO WHAT WAS SHOWN BY X RAY PICTURE

The Missouri Supreme Court holds, Bachman v. Quincy, O. & K. C. K. Co., 274 S. W. 764, that a doctor expert in taking x ray pictures, who took an x ray picture of the plaintiff in a personal injury action, and another doctor to whom he turned it over so that he could examine it and prescribe for the patient, were both competent to testify as to what the picture showed without having the picture before them at the time of giving their testimony, where the presence of the picture was disclosed, and the process of the court for its production was open to the other party if he desired it.

MEDICAL WITNESS ALLOWED TO LOOK AT UNIDENTIFIED X RAY PLATE

In a personal injury case reversal of judgment for plaintiff was sought on alleged error on the part of the trial court in permitting a medical witness, who was the plaintiff's physician and attended her at the hospital, to look at an x ray plate, which he was unable to say was a photograph of the plaintiff's leg after her injury, and to testify that an inspection of this plate refreshed his recollection as to the condition of the bones in plaintiff's foot.

The testimony was objected to on the ground that it was improper to permit the doctor to refresh his recollection by the use of a photograph that he could not swear was taken of the plaintiff's foot or leg. The New Jersey Supreme Court held, Hankelman v. Pasteelnick, 130 Atl., 441, that the objection was without merit, and that "anything which will refresh the recollection of a witness may be looked at by him for that purpose, although in itself it is not evidential."

AWARD BASED ON PHYSICIAN'S REPORT WITHOUT OPPORTUNITY FOR EXAMINATION HELD REVERSIBLE

The New York Appellate Division holds, Gannuzzi v. Foxwood Const. Co., 207 N. Y. Supp. 363, that it was error for the State Industrial Board to receive and act upon the report of a physician, received outside of any regular hearing, without the knowledge of the employer or insurance carrier, who were thus deprived of the right to examine the physician in respect thereto.

The Problem Method of Medical Teaching

The Repercussion

A. D. BUSH, M.D.
Emory University, Georgia

In the MEDICAL JOURNAL AND RECORD for June 17, 1925, I published the preliminary article entitled The Problem Method of Medical Teaching. It may be recalled that the opening sentence, and the keynote, was as follows: "At no time does one concentrate so thoroughly on the available data as when endeavoring to attain the solution of an absorbing problem, and at no time does one so take cognizance of pertinent facts as when equipping oneself to meet a definite situation." From this postulate I endeavored to outline the principles of a medical course consistent with such a postulate. Inasmuch as the medical course is essentially a vocational training, with such additional cultural values as may be incidental, it was suggested that the medical student would do best work if his studies all centred on or about actual clinical subjects. No attempt was made to suggest that the medical student should essay diagnosis until firmly grounded in the fundamentals, but it was contended that the teaching of these fundamentals might well be in relation to definite clinical problems.

The method as outlined in the preceding paper was that the student should be brought first into contact with patients carefully selected from the hospital wards and clinics so as to furnish a carefully graded series. The manifesting illness would be briefly discussed by the attending clinician, and the students then told to seek in their laboratories of anatomy, histology, pathology, and physiology adequate fundamental reasons for these particular manifestations; and when these reasons were found to return to this clinic for further discussion. A similar graded course covering the work throughout the present four years would be required.

In the preceding preliminary discussion no attempt was made to outline such a course; the principles only of such a course were there offered. A sample of the nature of the work (an assumed heart case) was presented, but solely to make more clear the nature of the argument.

Realizing the many difficulties that stood in the way of adoption of such a plan, it seemed best to ascertain the opinions of those presumably most interested. So reprints of the article, together with a brief printed questionnaire, were sent (with an addressed stamped envelope enclosed) to college presidents, deans of medical schools, professors of medicine, surgery, and pathology, presidents of all state medical societies, secretaries of all state medical societies, some general practitioners, and a few selected miscellaneous public men. Each one was requested, after reading the article, to express briefly his opinion as to the principles involved; the expression of opinion could be made by placing a mark adjacent to any of the five questions, to wit: 1. Do you unqualifiedly approve of this method? 2. Do you qualifiedly approve? 3. Do you qualifiedly disapprove? 4. Do you unqualifiedly disapprove? 5. Do you think the method feasible (or not)? Finally, what are your criticisms?

Three hundred and sixty-eight reprints with accompanying cards were sent out; 116 were returned, a percentage of return of 31.8. This, I am told, is a high percentage for questionnaire returns; I am constrained to believe, however, that there can be but two reasons why I did not receive one hundred per cent. returns; either the men addressed who failed to reply did not feel competent to make reply (as some admitted), or else they were more interested in something else.

The relative interest may be somewhat indicated by the following table:

	Number Sent Out	*Number Returned*	*Percentage*
College presidents	44	3	7
Medical deans	52	26	50
Anatomy professors	33	11	33
Surgery professors	33	11	33
Pathology professors	33	14	42
Medicine professors	33	9	27
Pres. med. soc.	54	13	24
Sec. med soc.	54	16	30—
General practitioners	24	5	31—
Miscellaneous	8	8	100
Total	368	116	31.8

The various attitudes of those who replied are fairly clearly indicated in the following table:

	Unqualifiedly approve	*Qualifiedly approve*	*Qualifiedly disapprove*	*Unqualifiedly disapprove*	*In doubt*
College presidents ...		2		1	
Medical deans	1	9	9	6	1
Anatomy professors..		5	2	4	
Surgery professors...	3	4	1	3	
Pathology professors	1	4	5	4	
Medicine professors.		6	1	2	

Copyright, 1926, by A. R. Elliott Publishing Company.

	Unqualifiedly approve	*Qualifiedly approve*	*Qualifiedly disapprove*	*Unqualifiedly disapprove*	*In doubt*
Pres. med. soc.	4	6	2	1	1
Sec. med. soc.	2	9		4	
General practitioners.		5			
Miscellaneous	2	3	1	1	1
Totals	13	53	21	26	3
Percentages	11.2	45.7—	18.1	22.3	2.5

From this table it will be seen that about fifty-seven per cent. of those answering favored the plan, more or less, eleven per cent. unreservedly; whereas about forty per cent. were opposed to the plan, twenty-two per cent. unreservedly. The major opposition was from the professors of pathology and from fifty-seven per cent. of the deans; the major support for the plan came from men more closely in touch with professional needs. The table will well repay study as showing relative attitudes.

Several of the writers contributed comments; when tabulated some of these comments appear as follows:

Too busy to answer	1
Such a plan would produce complete disorganization	2
This is the Toronto plan	3
It would require a tremendous supply of cadavers	5
It would be useful during the last two years	3
The fundamentals must be taught first	14
Too much taught now that is useless	6
It would require ideal faculty cooperation	9
Students of first two years unequal to such a plan	9
Would make technicians, not students	1
Good for later years	7
We need more homespun material	1
This is the best solution I have ever seen	3
It would take the best men from your faculty	1
The principle is good	11
All good teachers teach that way now	2
Well worth a trial	4
Too visionary	2
Chiefly a difficulty of administration	8
Not possible	2
Chaos would result	1
Correct idea but too much elaborated	1
Not feasible	67
Receipt of questionnaire acknowledged	12

Some of these comments deserve special reply at this time. The men who see in this plan a "chaos," "complete disorganization," a thing "not possible," or a thing "too visionary," are lacking in adequate imagination, or are superlatively conservative. The three who think this plan is like the Toronto plan are unfamiliar with the Toronto plan; the two are about as unlike as they could well be. Five anatomists are unduly perturbed about the cadaver supply, as this plan would demand no more cadavers than the present plan; it would require, however, close cooperation between anatomist and clinician, carefully graded work and dissection, and efficient embalming so that an assigned cadaver could be worked on for four years, and there would have to be adequate storage capacity.

If the plan would be useful during the last two years, why not during the first two? At least nine men think that the men of the first two years are mentally unequal to the task; this seems to me to be an utterly unwarranted aspersion. "But," say others, "the fundamentals must be taught first"; the plan anticipates the teaching of the fundamentals first. The problem method anticipates correlating fundamentals with clinical facts, teaching the fundamentals as they are concerned with the "case" observed. Under the present régime the student receives his anatomical fundamentals *en masse* with only such vague correlation as the teacher of anatomy may happen to know or choose to give; and the same remoteness of correlation between fundamental fact and clinical utilization is true in the courses of pathology, bacteriology, histology, physiology, and pharmacology—in fact, in all the fundamental branches as administered at present. But the problem method demands that there shall be a definite and tangible correlation in the teaching of each of the fundamentals and the clinical facts. The fundamentals must precede the clinical application; but let it be piecemeal and in reference to actual cases, and not *en masse* the way it is at present.

The difficulties of administration of the problem method are ponderous, it is true, but not insuperable. This difficulty of administration is recognized by many deans, by myself, and by many others who view the plan as not feasible. Cooperation by teachers of the socalled fundamental branches is difficult to secure; the requisite sacrifices by clinical teachers is not easily obtained. Yet tactful persuasion, coupled with appeals to relative values, will win over many. Of course there will be some teachers who place their own comfort, convenience or wishes above the needs of the students or the welfare of the people; there are some clinical teachers who primarily are profiteers. These must be slowly eliminated in favor of men who will place commonweal ahead of personal gain and ambition.

One dean wishes that I might experience the tribulations of deanship; I do not underrate them, but I do not consider them unsurmountable obstacles to progress. Another dean is peeved because my preceding article fails to give the details of effective administration; this first article concerned itself with underlying principles, if these are acceptable the details can be worked out readily.

One president, frankly acknowledging his personal lack of information concerning the problem, submitted the matter to one of his faculty. The report, as frankly and promptly indorsed by the president, was to the effect that no need existed for any such article as mine. This president, and his cloistered adviser, need to consult available literature; for example, they are referred to an article by the celebrated Chicago surgeon, Dr. Edward H. Ochsner, which appeared in *Science* for December 25, 1925. This article is entitled The Need of More Well Trained Practitioners of Medicine. Some pertinent excerpts are as follows: "Are the medical schools of this country today preparing their students primarily and principally for the services which the citizens of this country need most? Personally, my answer is no." "My opinion is based on an extensive experience with a large number of recent graduates." "One of the reasons why the medical student of today is so poorly prepared for the general practice of medicine when he graduates is because most of the teaching in medical schools is being done by nonmedical teachers and specialists." "The number of nonmedical teachers has increased to a point where it actually seriously interferes with proper medical education." If teachers will but consult available literature, or will consult practitioners, they will quickly find that present day methods of medical teaching do

not adequately prepare the students for the practice of medicine. Nor may the fifth year internship be looked upon as a satisfactory substitute for earlier deficiencies, valuable though this internship undoubtedly is.

Two or three correspondents think that "unless we continue to ground our students thoroughly in the fundamentals" the students will be unscientific, and cults and isms will increase apace. This line of argument presents many fallacies. In the first place, the present method does not ground the students thoroughly in the fundamentals; how much "Gray" does the senior student recall other than that portion pertinent to fourth year work? How much better it would be if the student's anatomy had been correlated with his surgery or medicine. In the second place the present method is less advantageous than the problem method in the matter of "grounding," unless we deny the truth of our postulate—that interest augments concentration. Third, there is no adequate evidence that the present method turns out scientific physicians, or that the present method is scientifically superior to the problem method; either point is widely debatable. The upholders of the present system are inclined to be ultraconservative, and ignore the fallacies so patent to others.

Closely related to the pedagogical standpatters are those who fail to recognize the fact that a medical school is primarily a place and opportunity for training men for the efficient practice of medicine. Say these: "The first two years are largely cultural." Any culture obtained during the first two years in the medical school is purely incidental; isolation of these years will not increase obtainable culture. Close our eyes to evident fact as we may, the truth remains that the medical school is, and ought to be, a technical school; a school where men are trained to be skilled members of society. The crowded curriculum has no place for purely cultural subjects, but those subjects only which aid the student to grasp applicable truth more strongly. Culture, as such, must be provided before the man enters medicine; medicine may be, and is cultural, but is not of itself culture; that is, it is not a general subject, one electable for its generalizing information, but a specializing subject that one pursues for particular purposeful training.

Some teachers of medicine (in the first two years, of course) are extremely jealous of their opportunity for developing embryo research workers; but as Ochsner caustically says: "Only an infinitesimal percentage of the general run of medical students will ever discover anything really worth while." Shall the balance of the medical student body, the medical profession, and that unknown but vast multitude that relies (more or less) on the medical science for its protection, become subservient to the speculative needs of these few? Only an individual pedagogically astigmatic can answer in the affirmative; yet I have heard the affirmative side upheld!

Concerning the relative merits of the thesis outlined in the article on The Problem Method the dean of one of the largest and most progressive state schools writes me as follows: "I am one of those who are gravely dissatisfied with the present arrangement and who feel strongly that the method of teaching the fundamental sciences is faulty. The amount of waste effort as compared with the very moderate result seems to me to be serious. I am quite clear that some method of bringing fact and application together is imperative. Your method seems to me a possible solution. I see as you do administrative difficulties, not the least of which will be the unwillingness of faculties to change habits respectable only because of antiquity. I am quite sure that some method involving the principle which you lay down is coming." This opinion is voiced by many of my correspondents.

The fundamental idea of the problem method is contained in the opening postulate: "At no time does one concentrate so thoroughy on the available data as when endeavoring to attain the solution of an absorbing problem; and at no time does one so take cognizance of pertinent facts as when equipping oneself to meet a definite situation." Does each teacher accept this postulate? Doesn't each teacher desire that his students shall concentrate maximally on assigned problems and take full cognizance of pertinent facts? Putting to one side personal predilections and prejudices does any teacher know of any demonstrated and therefore demonstrable method, other than the problem method, that will at once secure adequate concentration and cognition? If so, deans and teachers are anxious to learn about it; if not, why not enthusiastically embrace a method which will mean much to the student, even if it does seem to subtract a little from the teacher's *amour propre?* Let us be in the van, and work for the commonweal.

More Fallacies Concerning Hemorrhoids

J. F. MONTAGUE, M.D., F.A.C.S.
New York

In a previous article some popular fallacies concerning hemorrhoids were noted. There are submitted herewith some other views which are equally erroneous and apparently as widespread. Thus, I hold that it is erroneous to believe:

1. That hemorrhoids are hereditary. A distinction must be drawn between a hereditary weakness in vascular tissue and the inheritance of actual hemorrhoids.

2. That extensive preoperative catharsis and enemization is a necessary preliminary to hemorrhoidectomy. Patients do much better with the very simplest kind of preparation.

3. That it is necessary to "tie up" the bowels following a hemorrhoid operation. In the average case that has not been subjected to preoperative catharsis the patient will *not* have a bowel movement for two or three days even if tincture opii is omitted.

4. That hemorrhoidectomy cannot be done as completely under local as under general anesthesia.

5. That rectal wounds will always heal by first in-

tention if they are sutured at the time of operation. As a rule, infection of the wound occurs, the sutures slough out, and we have a worse condition than would have existed had the wound been left open.

6. That there is a capillary form of hemorrhoids. Pathologically, this condition consists in a teleangiectasis of the mucosal capillaries.

7. That there is an arterial form of hemorrhoids. This condition is often the remains of a partially cured hemorrhoid in which the venules have been obliterated but the artery remains. The structure is really a polyp.

8. That it is required by law that the first bowel movement shall be painful. There are simple measures which may be taken to make this event painless.

9. That the injection treatment of hemorrhoids is invariably followed by sloughing. When this treatment is properly administered, sloughing never occurs.

10. That the only cause of "piles" is constipation.

11. That hemorrhoids occur in children under three years of age. Most of these cases are really prolapse and not hemorrhoids.

12. That the general surgeon operates on hemorrhoids with the same care he would use on almost any other condition. Usually the junior intern, who is the most inexperienced man on the staff, has these cases assigned to him. If the general surgeon operates at all, in most instances he never personally treats his case again.

13. That the average graduate in medicine ever had presented to him even an elementary study of the commonest of rectal diseases—hemorrhoids. In some grade A schools, the course in rectal diseases merely has a place in the curriculum—a final resting place. The course itself is never given.

CONCLUSION

The foregoing terse statements of what I regard as false opinions concerning hemorrhoids are submitted for the constructive value they may have in inducing the careful consideration the condition warrants. There is no surgeon of average skill who cannot successfully operate upon cases of hemorrhoids nor is there any general practitioner of average skill who cannot intelligently treat cases of hemorrhoids. It is with a full consciousness of this fact that the statements given above are offered. Thus while not inpugning the professional skill of our medical colleagues, I *do* recommend a more careful consideration of these cases and the exercise of sounder judgment in coming to conclusions as to the nature of hemorrhoids and the consistency of therapeutic methods suggested for their treatment.

540 PARK AVENUE.

Some Notes on Cancer*

Abstract from a Series of Articles Now in Course of Publication

WILLY MEYER, M.D.
New York

The literature on cancer has engaged my special and continuous attention since 1920. The study has impressed me with the fact that the physical aspects involved in the cancer problem seem to be of no less importance than the chemical ones and deserving of the most searching consideration. The study has also resulted in certain thoughts on the genesis of cancer, points of view—not theories. These points of view I have attempted to set forth in detail and with supporting references from the literature in a series of articles under the title given above. The contents of the series, especially the physical features, are condensed in the following paragraphs, all references being here omitted for the sake of brevity.

1. *The general viewpoint of the series.*—We have inherited cancer as a problem. Our forbears left it to us high up on a pedestal of exceptionalism and unapproachableness from which it frowns down upon us. The time has come, I believe, that we should repudiate the legacy. Cancer should come off its pedestal; it should be brought to earth; it should be made amenable to common medical conceptions.

Can this be done? It would appear not to be a hopeless task, in my judgment, to find a way of explaining cancer as we explain everything else in medicine, as a reaction; in this instance, (with the emphasis on the physical aspects) as the ordinary reaction of certain cells to changes in their environment.

Against this background the series has been built up. Papers of general review are followed by articles on the theoretical questions involved, and in a final article, on practical questions of therapy, the gained conceptions are tested on the basis of personal clinical experience, and on the experiences of others taken from the literature.

2. *Predisposition.*—The literature contains the deduction—from comparatively very small material, it is true—that about one fifth of all civilized human beings are predisposed for cancer. For our country, one fifth of the population would mean about twenty million predisposed persons, and as we are supposed to have with us constantly about two hundred thousand cases of malignant disease, these approximations would seem to indicate that about one per cent. of those predisposed are actually seized with cancer.

There seems to be a general and a local predisposition. General or systemic predisposition appears to be principally chemical; local predisposition, or the predisposition of individual organs, largely physical.

Local predisposition becomes manifest in the fre-

*A fifteen minute abstract of this abstract has been read, under the title, Thoughts of a Clinician on the Genesis of Cancer, before the nineteenth annual meeting of the American Association for Cancer Research, Albany, April 1, 1926.

quency of seizure with primary cancer of some organs, and the comparative immunity therefrom of others. The cause of the phenomenon appears to be mostly physical. Ordinarily immune are, it would seem, the organs which are actively at work more or less all the time: the heart, the spleen, the small intestine; in animals, e. g., the mammary gland of a dairy cow. In the lungs, the constantly moving parenchyma is hardly ever, the resting bronchial tree not infrequently, seized with primary cancer.

The importance of physical considerations seems to stand forth also from the predilection of solitary metastases for restful sites, such as the spongy bone of the vertebræ, the ends of the long bones, etc. The difference in the physical condition of the sites of predilection for, and of comparative immunity from, primary and secondary cancer would seem to reside in the respective degrees of activity of their circulation of blood and lymph, rapid circulation apparently going with immunity, sluggish circulation with seizure.

On the chemical side of predisposition I believe the genesis of cancer to be largely bound up with an unbalanced state of the salts of the serum; on the physical side with stagnation (see paragraphs 5 and 6 below). We are probably justified in stating: Without predisposition, no cancer!

The apparent exception (the development of sarcoma after a trauma in a perfectly healthy person) probably finds its explanation in the unbalancing of the salts of the serum by the trauma itself. Only when the trauma is sufficiently severe to be capable of producing the change of the serum does a sarcoma seem to develop under such circumstances.

3. *Release of the process and onset of the precancerous state.*—When in a generally predisposed person a locally predisposed organ becomes subject to the attack of a cancer inciting factor, i. e., to any factor capable of causing acute cell death, the reaction of the organ thereto would ordinarily seem to depend less on the nature of the assaulting factor than on the nature of the assaulted person. In a normal individual the lesion may heal and that will be the end of it; but in a predisposed person the lesion may heal imperfectly or may not heal at all, the abnormal reaction leaving behind it in the first instance an external or internal scar formed of tissue more or less pathological; in the second instance an open sore, an ulcer, a fistula, an eczema and the like; all of which residuary conditions are states of chronic irritation.

The rôle of the cancer inciting factor—which, from the viewpoint of the attacked cells, is always an external influence, be it exogenous or endogenous—has now been played. The acute phase of the process with its multiplicity of variegated and, among themselves, unrelated inciting factors has come to an end. The effect of the performance of all these inciting factors, different though they be individually, is probably always one and the same end result, namely, some kind of a chronic irritation. If the attack of such a factor upon a predisposed person does not result in chronic irritation, then that is likely the end of it, and nothing further happens; but if it does result in chronic irritation, then, beginning with that event, the subsequent process would seem to stand under the sway of always one and the same real and permanent cancer inciting factor—the chronic irritation. Henceforward the process would seem to be in its entirety always and completely internal. At this point, I believe, lies the onset of the precancerous state.

4. *Cancer inciting factors.*—What in the past has ordinarily been termed "cancer inciting factor" is stamped by the foregoing discussion as something pre-precancerous. Inasmuch as the precancerous state appears as a phase of doubtful outcome, because the process leading from the chronic irritation up to and including the beginning of malignancy may during any phase of the precancerous state be derailed and cease, obviously, the term "cancer inciting factor" is a misnomer for the factors which produce the acute lesion. All these numerous factors can have no direct bearing on the development of the cancerous process, for, whether their nature be chemical, physical or bacterial, whether it be an acid burn, a blow, a ray, or any kind of a bacillus, etc., these inciting, or perhaps better, "enacting," factors, are always as far removed from being the true inward cause of cancer, as the match which lights a grate fire is removed from being the cause of the heat which radiates from the burning coal. The term "cancer inciting factor," it seems to me, had perhaps better be reserved for the actual cancer inciting factor—the chronic irritation.

Restating the foregoing briefly: Upon the assault of the acute irritant (ray, tar, bacillus, etc.) the predisposed individual is apt to react with a chronic irritation, which latter then, in turn, becomes the irritant and elicits a secondary chronic reaction of the individual—and it is quite conceivable that this process should be repeated more often than twice, so that chronic reaction would be superimposed upon chronic reaction before at length the reaction occurs from which the precancerous developments originate. If this be correct, then the absolute futility of the search for the cancer bacillus would seem to become plainly apparent, equally so the search for the cancerogenous tar factor, or for any other (from the point of view of the cell) external factor, including embryonal rests, as the direct cause of cancer.

As far as bacilli are concerned, the only justifiable questions regarding their relation to cancer genesis would seem to be: 1, How do bacilli produce and maintain a chronic irritation? 2, In what does this chronic irritation consist?

5. *Reaction to chronic irritation.*—We have now reached the question: How in a generally predisposed individual does a locally predisposed organ react to chronic irritation? The reaction seems to be twofold. At the irritated spot the organ probably reacts, first, with a focus, or foci, of microscopic size, formed by the occlusion of the smallest local bloodvessels by stasis and of the surrounding lymph spaces by coagulation, both being eventually completely obliterated and the foci thereby walled off from the general medium; second, with chronic cell death in the foci.

It will be noticed that here we come for the second time in the process upon cell death. The first, *acute* cell death was found to have but a mediate relation to the process. This second, *chronic* cell death, to the contrary, in conjunction with the stagnation prevailing in the foci, appears as the factor probably underlying the cancerous process, as follows:

6. *Cell decomposition products.*—The cells killed in the foci by the chronic irritation undergo therein necrobiosis[1] and split into decomposition products of protein, the quantity of these products depending on the number of cells killed, i. e., on the intensity of the chronic irritation. The rapidity of the accumulation within the foci of the protein decomposition products depends on the degree of stagnation in the foci, this in turn, on the degree of impermeability of the foci, and the latter again on the intensity of the chronic irritation, so that in the last analysis the degree of chronic irritation governs. As it fluctuates, so necessarily fluctuates everything reacting thereto, including the strength of concentration of the cell decomposition products in the foci.

Immune organs are likely immune for the reason, in part, that their strong circulation prevents the formation of foci, or, if formed, prevents the foci from attaining a degree of impermeability sufficient to make possible the increase of concentration of protein decomposition products within them. The stagnation is missing.

7. *Cell decomposition products enforce cell multiplication.*—Decomposition products of protein have been found to induce the division of cells exposed to their influence, and the rapidity of cell multiplication has been found to increase with the degree of concentration of the products. In the case in hand the necrobiosis is assumed to take place in the foci. According to the degree of their occlusion, more or less complete stagnation supposedly prevails in the foci. The decomposition products within them have thus a chance to increase in strength of concentration. As soon as this degree exceeds, within the foci, the threshold of physiological tolerance of the exposed cells, these latter face the alternative of "die or divide," that being all a cell can do under the circumstances. If it survives, and if it is to survive, it must divide, and so must its daughter cells and generations of their descendants, because, on coming into existence, all these newly formed cells find themselves faced by the same focal medium which enforced the division of their progenitors. The cell multiplication evidently continues until cells arise which are in equilibrium with the focal medium, the latter then ceasing to be a stimulus of division for them. The multiplication of cells under the influence of the focal medium appears to be enforced upon the cells, and the part taken by a cell in its division seems here to be inert. Cell division in cancer is in all probability a passive phenomenon.

8. *Cell crowding.*—The question arises: How do the newly formed cells react upon one another? Inasmuch as all these cells are known to be lying loosely in the tissue, the demand for space of those last formed would appear to become a *vis-a-tergo* which pushes those previously formed out of the way. The movement of changed cells, starting from the foci, which is seen to occur in the tissue in the direction of least resistance, is supposedly due to this pushing from behind. The quantity of moving cells, and therewith the degree of cell crowding, depend on the rapidity of cell multiplication, i. e., as stated, on the degree of concentration of the focal medium.

[1]According to Virchow, necrosis means sudden cell death, the necrotic mass remaining in the tissue as a foreign body; "necrobiosis", slow cell death, the cells undergoing lysis in the tissue fluids and disappearing, leaving behind a defect.

Just beyond the threshold of physiological tolerance the proliferative process would probably amount to no more than a mild hyperplasia. From this minimum of cell crowding the proliferation would seem to rise with increasing strength of concentration of the focal medium, fluctuating as its degree of concentration fluctuates, and to attain eventually through an unbroken series of imperceptibly graded benign intermediate stages to the maximum of cell multiplication and consequent cell crowding, malignancy. Thus the motility of cancer cells and their accumulation in the tissue appear also as an enforced, as a passive phenomenon. Considered from the physical viewpoint alone benignity and malignancy would seem to appear merely as different degrees of cell crowding.

For the chemical aspects of the matter the reader is referred to the original articles.

9. *Growth in cancer.*—There is a fourth probably passive factor involved in the process of the development of cancer, namely growth. Is the term growth definite and clear cut? There is, first, the growth, e. g., of a green leaf, physiological growth, in which that which grows takes an active part. There is, second, the growth, e. g., of a heap of dead leaves, in which the part taken by the falling leaves in making the heap grow is passive, as is also the part taken by the heap itself in growing. So there is active growth and there is passive growth; active growth, in which that which grows, e. g., a green leaf, does everything; passive growth, in which that which grows, e. g., a waste heap, does nothing.

10. *Cancer a passive growth.*—A viewpoint has now been gained without resort to extraordinary assumptions, the whole argument being based on common medical conceptions, from which the factors, incessant cell multiplication, cell motility, cell accumulation and, as embodying all three, tumor growths, appear not as autonomous, anarchic, unaccountable, mysterious phenomena, but as the enforced reaction of cells to changes in their environment.

From this point of view a carcinoma appears as a waste pile of changed, living epithelial cells, the parenchyma, which have been pushed passively into the preformed interspaces and lymph channels of the connective tissue, the stroma, forced into them passively, because at the primary site of trouble the focal medium is believed to enforce cell division at such a rapid rate that the previously formed new cells are being crowded by the demand for space of the younger generations of new cells, and because by this *vis-a-tergo* the older cells are being pushed into whatever space offers a refuge.

Viewed from the physical angle, the question, from whence do cancer cells derive their growth energy, would seem open to a different interpretation than hitherto suggested. It has been observed and verified that growing cancer cells and resting epithelial cells have practically the same intake of oxygen. This observation appears to me to be the strongest kind of confirmation of the contentions here submitted. Those who made the observation looked at the matter from the chemical point of view; they accounted by the fermentative action of cancer cells for the supposed discrepancy in energy consumption. From the physical point of view, on the other hand, there appears to be here no deficiency of energy at all. The seemingly actively growing cancer cells use

no more oxygen than resting epithelial cells, because from that point of view they, the cancer cells, do not grow; because they, too, are believed to be resting; because probably nothing they do is active; because in whatever they do, be it multiplication, motion or accumulation, they seem to be using no energy of their own; because whatever energy they possess is probably imparted to them. What is really growing in cancer is, it seems to me, not the cancer cells, but their waste pile.

11. *Therapy.*—The question naturally arises: What benefit is there in looking at cancer from this point of view? If there is any virtue in the assumption of stagnation being an associated factor at the root of the process of cancer, then the obvious therapy for inoperable cancer—operable cases remaining emphatically the domain of the surgeon—would seem to consist of the restoring of the circulation of blood and lymph in, through and around the new growth, for the purpose of diluting the focal medium and of thus nullifying its cell multiplication enforcing effect.

Therapeutic procedures already empirically employed in unquestioned cancer cases, such as various means for turning the chronic into an acute inflammation, among them multiple scarification, cauterization and the like, would all seem to tend in that direction.

If returning improved circulation has a tendency to heal the cancerous process, as sometimes observed, then the assumption can not be far from the truth, that inhibited circulation—stagnation—was involved in causing the original lesion. Observed cases of spontaneous healing may, in part, also be referable to restored circulation.

But after even the complete regression of the new growth there would still remain the general predisposition of the patient to be taken care of. Here we come to one of the chemical aspects of the problem. General or systemic predisposition is probably always alkalosis, i. e., the overbalancing effect in the salts of the serum of potassium. Calcium being the antagonist of potassium, an intensive calcium therapy would appear indicated. This has already been suggested by others, and, in fact, sporadically practised in actual patients. But the administration of small doses of calcium at frequent short intervals over long periods of time would also appear indicated as a prophylactic treatment for suspected cases and for individuals with a family history of cancer, and further for all other persons in general, whose reaction on blood examination was found to exceed the normal alkalinity. Just how to administer calcium effectively has still to be learned, and the whole question of predisposition is in need of a more reliable statistical foundation.

12. *Blood examination.*—In view of what has been said, it is recommended to extend all examinations for blood chemistry to include, as a matter of routine, the testing for reaction, for salt content of the serum and for the percentage composition of the salt content.

As stated in the beginning, the facts used in the foregoing presentations are taken from the literature and the references are duly quoted in the original articles.

The Palliative Treatment of Inoperable Cancer

JOSEPH K. NARAT, M.D.

Chicago, Ill.

While a great deal of work has been done in the last few decades on the development of the surgical and radiological treatment of cancer and in the experimental study of malignant neoplasms, the palliative treatment of cancer has received less attention than it deserves. It is superfluous to make the assertion that the only rational treatment of cancer is an operation, in suitable cases substituted or supplemented by irradiation. But a great number of cases are inoperable—a deplorable fact due either to the extent or localization of the tumor or to some concomitant ailments, such as certain heart diseases, diabetes, nephritis, and other conditions. In regard to these cases a fatalistic point of view prevails among the medical profession. The physician limits his action to prescribing narcotics and referring the patient to a röntgenologist. No wonder these unfortunate sufferers fall into the hands of selfappointed cancer specialists and other widely heralded charlatans who put forward unjustified claims of cancer cures. The therapeutic nihilism of the physicians should be dropped and a rule adopted to make the most strenuous efforts to carry the patient through the natural course of his disease with the greatest obtainable comfort, relief from pain, and other distressing symptoms. In order that the crusade against cancer be successful, it is of the utmost importance, not only to arouse the public to the necessity of an early diagnosis and treatment of cancer, but also to create in the medical profession the feeling that even in incurable cases of cancer much can be done for the patient without resorting to uncertain or useless agents and remedies.

Much stress should be laid upon the systemic treatment of the incurable cancer and the necessity of building up the resistance of the diseased organism.

General hygienic rules must be observed. Attention is to be paid to the temperature of the daily bath, especially in patients with external cancers, as hot water causes hyperemia and thus may promote the rapid growth of the tumor. Therefore, the temperature of the water in the bathtub should be kept as low as possible without causing an unpleasant chilling of the body.

If the patient cares for massage, the involved area should be carefully avoided by the masseur because the vigorous manipulations stimulate the growth. Dietary regulations should be rigidly enforced. The influence of the diet upon the growth of cancer in human beings has not yet been studied sufficiently, but

experiments on animals reveals that the diet is an important factor in the development and progress of malignant neoplasms. A diet rich in carbohydrates stimulates the growth, as has been shown by Haendel and Tadenuma (1-2); potassium in the diet has a stimulating effect, calcium retards the growth. A simple diet, free from or containing a small amount of animal proteins, is to be recommended. Cooked vegetables should form the bulk of the dietary of the patient, with abundance of fruit (except sour apples and grapefruit) and cereals; excessive use of coffee, spices, condiments, beans, sauerkraut, uncooked tomatoes, fresh bread should be forbidden. A thorough mastication must precede deglutition, especially in cases of cancer of the gastrointenstinal canal. Cachexia, whether regarded as a result of the production of toxins by the problematic cancer germs or of the action of unknown ferments or toxic products of metabolism, is a process of retention and resorption. To combat it, a large amount of distilled water either plain or with fruit juices should be taken. Charged drinks and alcoholic beverages are not advisable. It is not difficult to restrict the diet of the patient according to these rules without depriving him of the culinary enjoyments.

Persistent constipation is a factor in the etiology of cancer as put forward by Pauchet, Sir Arbuthnot Lane, Robert Bell and others. If the bowels do not move freely in spite of a liberal use of hot water and fruits, a mild physic should be taken, e. g., liquid petrolatum. The saline laxatives such as magnesium citrate, magnesium sulphate, sodium phosphate, epsom salt, should be avoided because due to their hygroscopic action they deplete the body by withdrawing from the cachectic organism a large amount of water.

One of the greatest problems the physician has to face in the palliative treatment of cancer is the pain. It should never be forgotten that the neurotic element enters into the complaints of many patients as in every chronic ailment; various bromide preparations give relief in such cases. Where the pain is not severe, suppositories containing antipyrin five grains and extract of belladonna one sixth of a grain are helpful. When the use of narcotics is unavoidable, the opiates should be saved for the later stages of the disease, otherwise the patient becomes so used to them that when the pain increases with the progress of the disease, no drugs will give him relief. The barbital group can be tried first; luminal-adalin tablets are effective in moderate degree of pain. If morphine has to be resorted to, preferably it has to be given by mouth or by rectum and the hypodermic injections spared for the latest stages of the disease where the prospective span of life is short. In extremely severe pain a combination of morphine with magnesium sulphate gives the best results. A syringe should never be placed in the hands of the patient. Once in a while a hypodermic injection of distilled water or saline solution may be given instead of the customary morphine injection with the same beneficial result.

In cancer of the oral cavity the selection of a suitable mouthwash is important; more attention has to be paid to the soothing than to the refreshing properties; most of the patent mouthwashes contain menthol, eucalyptol, thymol, and other irritating substances. Boric acid or still better an infusion of leaves of salvia—one tablespoon to six ounces of water—meets the requirements for a good mouthwash; where friable, decaying masses are present in the oral cavity, this mouthwash may be alternated with a two per cent. solution of tannic acid.

In cancers of the esophagus which are nearly always inoperable, the irradiation should not be relied on, but in addition to it a gastrostomy performed under local anesthesia. The feeding through the tube saves the sometimes ulcerating cancerous masses from contamination by germs carried with swallowed food particles and prevents the starvation of the patient. The impossibility of the ingestion of food affects greatly the mental balance of the sufferer; he should be allowed to chew the food and to eject it into the funnel attached to the gastrostomy tube; a syringe may be necessary to push the food through the tube into the stomach. The mastication supplies the saliva important for the predigestion of the food and according to the famous experiments of Pawlow causes secretion of appetite juice in the stomach. Spices, condiments, highly seasoned foods, cold drinks should be avoided; the patient may be given milk with cream, tea, weak coffee, all kind of cereals and vegetables, broth, fruit, preferably cooked, calves' brains, small pieces of chicken, lamb or veal.

In cancers of the stomach one remedy which was highly praised two decades ago and then fell into oblivion frequently relieves the distress in the epigastric region and improves the appetite; it is vinum condurango—one teaspoonful three times daily before meals. Where severe pain is present, large doses of bismuth should be tried before resorting to narcotics. In gastric hemorrhages a lavage with very hot water is more effective than the use of cold water; a few drops of adrenalin solution one to a thousand may be added. Application of heavy sandbags over the epigastrium frequently checks the hemorrhage instantaneously.

In inoperable cancers of the rectum a palliative operation—colostomy—is often indicated; it can be performed in a few minutes under local anesthesia; the operation relieves the cancerous masses from the constant irritation of fecal material and from the resulting congestion of the mucosa; the life may be prolonged, the pain diminished and the application of radium facilitated. Low enemas should be employed daily to remove the necrotic, foul smelling masses; warm chamomile tea serves this purpose best. In hemorrhages resulting from the cancerous growths of the urinary bladder heavy sandbags should be applied to the hypogastrium; they are much more effective than the icebag. This treatment may be supplemented by a lavage of the bladder with hot water; icewater also has hemostyptic properties, but it irritates the bladder and causes distressing symptoms. Adrenalin has little effect, probably because of the lack of elasticity of the bloodvessels within the hard cancerous masses. The instillation of a few cubic centimetres of blood coagulant of animal origin, such as thromboplastin, coagulen, or fibrogen, through a soft rubber catheter may prove successful. Intravesical procedures such as thermocautery or diathermy, belong to the domain of the genitourinary specialist.

As to the local treatment of external cancers, the principle should be carefully observed not to apply any remedies which may irritate or stimulate

the granulations; ointments containing scarlet red, silver nitrate, or balsam of Peru have to be avoided. Various arsenic pastes have been used for local applications since ancient times. Probably the best known form of these applications was the Zeller's paste which contained arsenic and mercury; Zeller recommended silicium internally in addition to the local use of his paste. Intoxications from the absorption of arsenic paste has repeatedly been observed. Its beneficial action depends entirely upon the depth to which tissue is destroyed.

Among the liquid caustics chromic acid occupies a prominent place; it inflicts relatively little pain and checks to a certain extent the excessive growth of the cancerous tissue. Formalin also has therapeutic value in the palliative treatment of the cancer. According to the recommendation of Powell (3) it should be used in a two per cent. aqueous solution which is prepared by adding nineteen parts of distilled water to one part of commercial formalin.

A more modern palliative treatment of cancer consists of the application of salt paste which was first recommended by Martenstein for the treatment of lupus vulgaris. Andersen (4) suggested its use for the local treatment of cancers, basing his theory on two considerations. First, a retention of chloride is known to be a general method of defense of the organism, seen in various infections, inflammations and other pathological processes; furthermore, according to the Arndt-Schultz's law, an excess of salt damages the cell to such an extent that the destructive process becomes irreversible and the cell perishes; second, the greater the salt contents of the tissues, the greater their susceptibility to irradiation; therefore, an impregnation of the morbid tissue with salt previously to the application of the x ray or radium may increase the sensitiveness of cancer to the action of the rays. A layer of salt paste one quarter to one half cm. thick is applied to the cancerous masses and the surrounding tissues protected with borvaselin. The formation of an eschar is prevented by covering the dressing with wax paper or some other impermeable substance. To stimulate the demarcation and elimination of the necrotic masses, a three per cent salicylvaseline is applied after a few days. There are two disadvantages of this method: first, a parenteral salt fever, well known to pediatrists, may occur; second, the treatment is painful and causes thirst and local edema. However, judging from the reports published by Andersen, the salt paste seems to have a remarkable influence upon cancers, at least retarding the progress of the growth and it is worth while to apply this method in suitable cases.

The fetor is frequently one of the most annoying symptoms of the cancer—it affects the patient himself as well as his family. In the control of fetor excellent results may be obtained from the local applications of granulated sugar; the only objection to its use may be the fact that the absorbed sugar can serve as nourishment for the cancer cells and thus contribute to their rapid growth and multiplication. Therefore, its use should be confined to very advanced stages of the disease. Equally beneficial results may be obtained from the use of powdered coal of animal origin (*carbo animalis*), which has great deodorizing properties. This socalled kitchen treatment (salt, sugar, coal) is valuable in combating the sometimes profuse discharge and the terrific fetor of cancerous masses which make the patient unbearable to society and his own family.

For the same purposes two other substances may be used as a dusting powder with gratifying results—permanganate of potassium and resorcin. The latter also has analgesic and antiseptic properties. It is surprising how the control of fetor improves the color, the appearance and the mental condition of the patient.

Among the physical agents phototherapy in the form of sunlight may be applied as a deodorant by means of a concave mirror, as employed by William Becker (5). The thermocautery also destroys the necrotic tissue and may be used not only for the radical removal of the neoplasms, but also in inoperable cases to check at least temporarily the rapid growth of cancerous masses. The use of medical diathermy is generally not advisable for the palliative treatment of cancer, as the rise in the local temperature of the tissues causes an active congestion and stimulates the growth; surgical diathermy plays an important rôle wherever radical destruction of the cancer is attempted.

There is an endless number of methods of treating cancer, but most of them are of very problematical value. Mineral cancer cures, such as the use of lead, recommended by Blair Bell, gold, introduced by Ruportail and Duparcque, were formerly in vogue, but have fallen into discredit and are newly invented every few years. The biological methods, e. g., various sera, toxins, ferments, as well as chemotherapy and bacteriotherapy, seem to have as yet little therapeutic value.

CONCLUSIONS

It cannot be too strongly emphasized that an early operation is the only procedure that has been proved to be a cure for cancer and that postponement of an operation by a physician who made a correct diagnosis should be regarded as criminal negligence. From the foregoing review of methods recommended for the palliative treatment of cancer the conclusion may be drawn that in inoperable cases the fatalistic point of view and the prevailing pessimism are not justified and that much can be done to relieve the most distressing symptoms such as pain, discharge, fetor. The task of curtailing the pernicious activities of irregular practitioners and other unscrupulous persons and of preventing the unfortunate patient from adopting various cults and pseudosciences can be accomplished only by the proper education not only of the public but also of the medical students. A special course on cancer should be included in the curriculum of every medical school; such a course should comprise the various theories of the origin of cancer, its surgical, radiological and palliative treatment.

Multiple Osteochondromatosis

J. EPSTEIN, M.D.,
New York

Children are comparatively immune to neoplasms. Of the new growths that do occur in early life, tuberculoma, glioma or gliosarcoma may affect the brain. Sarcoma, hypernephroma, carcinoma and cysts may start in the kidneys. The liver may give rise to carcinoma, sarcoma and endothelioma. The spleen, intestines, peritoneum, lymph glands and testes may be the seat of various benign or malignant growths. Bone may give rise to osteoma, while cartilage may produce chondroma or osteochondroma as in the following case which is reported because of its rarity, unusual multiplicity, and destructiveness.

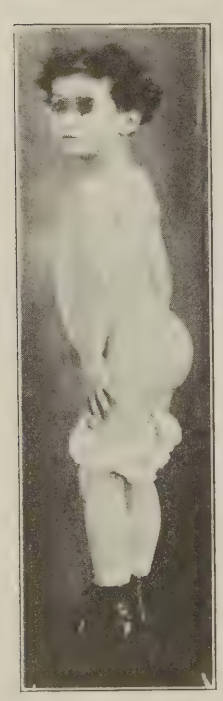

FIG. 1. — Multiple osteochondromatosis. Child six years old. Marked lumbar lordosis, causing the body to be thrown forward and the buttocks unusually prominent. Some bony tumors could be seen at the wrist and at the upper third of the humerus.

CASE.—B. R., a girl aged six. The family history has no bearing upon her condition. She was born in Russia during the political upheaval, at a place where the population was extremely harassed and food and shelter were exceedingly bad. She was of full term, normal birth and breast fed for seven months. Then she was fed on whatever food could be obtained. The general development was slow and she began to walk at two years of age. At that time it was noticed that her gait was wabbling and she had difficulty in moving the left leg. A short time after, it was found that she had little hard growths along various bones. During the last two years she had scarlet fever, measles, and chickenpox.

On examination, at the age of six, the child appeared small but of fair mentality. She limped on walking, dragging the left leg. There was a marked lumbar lordosis with an unusual displacement backward of the hip joints as is shown in Fig. 1. The head was of the rachitic type with no tumor growths. There were no gross deformities of the chest. Beginning with the clavicles and tracing downward along the ribs and the upper and lower extremities, the skeleton was found to be studded with hard irregular painless tumor masses ranging from some that were two by four cm. to others that were barely palpable. They were bilateral and more or less symmetrically arranged localizing mainly at the costochondral junctions and at points of greatest bone growth, as is shown in Figs. 2, 3, 4, 5. The left hip joint was ankylosed and the left leg was shorter by one half inch. Both ulnar bones were shorter than their corresponding radii. There were no fractures. The internal organs were normal and there were no abnormalities of the teeth, lymph glands, thyroid or thymus. The blood count and the urine examination showed nothing abnormal. The Wassermann and the tuberculin tests were negative. The calcium and the phosphorus content of the blood were respectively 11.6 and 3.95 mg. per 100 c.c. of blood. Weight forty pounds. Height thirty-three inches.

ETIOLOGY OF OSTEOCHONDROMA

This type of neoplasm is of special interest because of its occurrence in early life as a congenital or acquired new growth, its tendency to wide distribution, and its regressive character when the period of skeletal growth has reached maturity. It is caused by some disorder in the growing cartilage. Through some abnormal stimulation a number of scattered bits of cartilage proliferate, giving rise to multiple benign tumor growths. Osteochondromatosis seems to bear some etiological and pathological kinship to rickets, osteochondritis and chondrodystrophy.

Osteochondromata, whether originating from normal cartilagenous areas, or from misplaced islands

FIG. 2.—A large calcified cartilagenous tumor in the head and neck of the left femur with marked coxa vara. A similar growth but of lesser degree at the right femur.

of cartilage, always produce their respective type of cartilage which, in the majority of cases, is of the hyalin variety. From the periosteum the tumors may grow into the medullary cavity or they may push their way outward. In some cases, they may be medullary in origin and grow within the canal. The

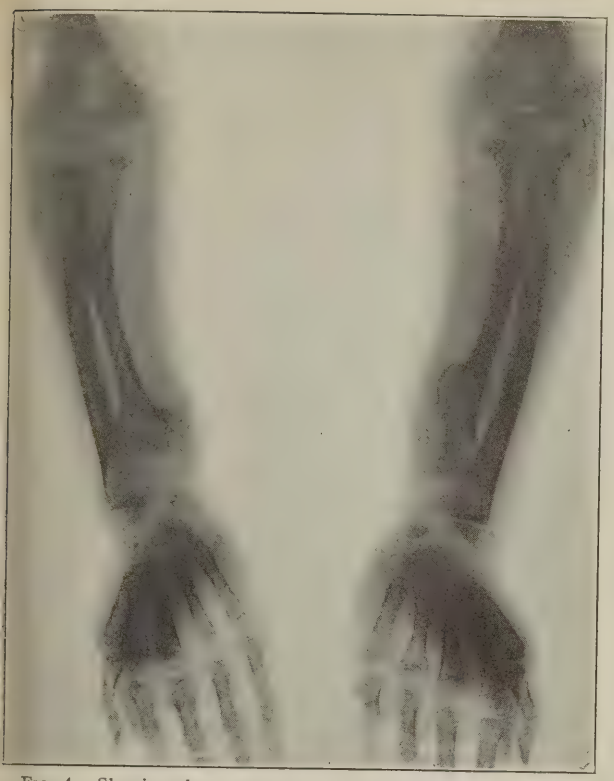

FIG. 4.—Showing the presence of tumor masses at the upper and lower ends of both tibiæ and fibulæ in osteochondromatosis. Same case as in Fig. 1.

FIG. 3.—Both ulnar bones are shortened at their lower ends and terminate in tumor masses. There is also a tumor at the lower end of the right radius.

lesion usually affects either end of a long bone and produces cartilagenous, cauliflower growths. After reaching a certain stage in development they undergo calcification. While occasionally osteochondromata are of the nature of a simple hyperplasia, and are few and limited, generally, however, they are of the character of a true neoplasm, widely spread, but not malignant. Malignancy, though rarely, may occur.

DIAGNOSIS

The diagnosis of osteochondromatosis rests on the nature and consistency of the tumors, their multiplicity, and their tendency to affect chiefly the long bones. Pathological fractures are not uncommon and are of diagnostic importance. The röntgen ray is essential to a correct diagnosis. It shows a proliferative, multilocular, cysticlike growth with sharply limited borders. Osteochondromatosis should be differentiated from exostosis, deforming osteochondritis, rickets and chondrodystrophy by the clinical course and by the röntgen ray findings. The absence of new bone formation is against exostosis. Flattening of the epiphysis of a hip joint is typical of deforming osteochondritis. Epiphyseal saucershaped expansion is present in rickets and a general stunting of bone growth is diagnostic of chondrodystrophy. The age period is important, as osteochondromata are seen most commonly between the ages of five and fifteen years. Whether in this case the osteochondromatosis was of congenital origin or was acquired in early life as a result of the extremely bad conditions of living, is difficult to tell. The fact that the disease was noticed very early in life points to a congenital origin.

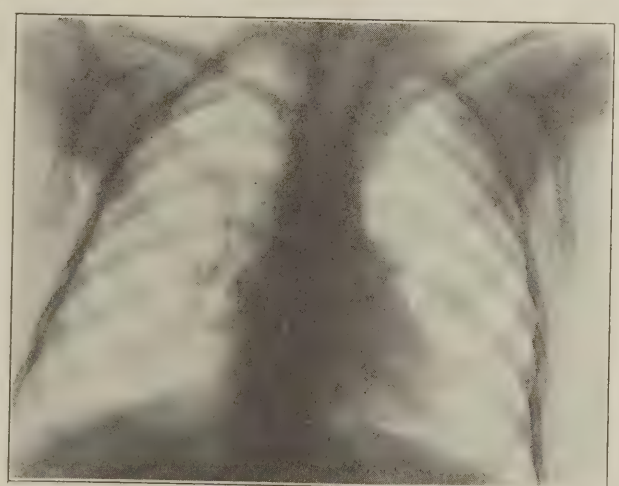

FIG. 5.—Osteochondromata at the inner ends of both clavicles, lower angles of scapulæ, upper third of both humeri, anterior end of second rib on right side and first and second rib on left.

PROGNOSIS

The prognosis depends on the nature of the tumors, whether benign or malignant, their size and location and the amount of damage they may do to the internal organs. Tumors arising from the cartilage of the respiratory tract or those invading the medullary cavity or affecting the joints or pressing on the central nervous system have a poor outlook.

TREATMENT

There is no specific or definite treatment for these cartilagenous growths. Thyroid and actinotherapy may be tried.

A Case of Pyelonephritis with Persistent Hematuria

LEOPOLD VACCARO, M.D.

Philadelphia

Pyelonephritis is ordinarily described as an advanced stage of pyelitis in which the inflammatory process involves the renal structure proper, as well as the pelvis and calyces of the kidney. The case we are presenting, besides illustrating a typical case of pyelonephritis, is remarkable because of macroscopic hematuria persisting for nearly two months, a rare occurrence. It might be profitable to precede the case presentation with a few general remarks on pyelitis.

ETIOLOGY

The exciting cause of pyelitis is usually the Bacillus coli the Bacillus tuberculosis or the gonococcus. The other less frequent organisms are the staphylococcus, streptococcus, and pyocyaneus. The first three named bacilli produce acid urine and the others alkaline.

There are numerous predisposing factors, such as torsion of the uterus, renal calculi, neoplasms, pregnant uterus, all causing blockage with subsequent retention and renal pelvic inflammation. The rôle of the pregnant uterus in the causation of pyelitis is discredited by some gynecologists who maintain that pyelitis, in obstetrical practice, occurs in early as well as late pregnancy, rendering induction of labor for the relief of pyelitis of doubtful value. Others, on the other hand, justify the emptying of the uterus in certain selected cases, because of the intimate relationship of pregnancy and proper renal function.

In childhood, pyelitis is often associated and confused with enteritis. It would appear that the colon bacillus travels through the lymphatics into the kidney pelvis setting up an inflammation. However, insufficient studies have been made, both serologically and biologically, to determine whether the Bacillus coli is exogenous or endogenous. The Koch's bacillus seems to follow the hematogenous route and very rarely ascends from the lower genitourinary tract. Leon Herman believes that tuberculous cystitis is usually secondary to kidney infection. Girls are more often affected than boys.

The ascending route is chosen by the gonococcus. Occasionally acidity or alkalinity of urine may induce pyelitis, also residual urine in apparently normal bladders may induce pelvic infection. Cold and damp are also etiological factors.

SYMPTOMS

The symptoms of pyelitis are usually irregular fever, pain in the lumbar regions, unilateral or bilateral tenderness, with the possible detection of a soft mass produced by kinking of the ureters or subcapsular collection of pus. Emaciation, secondary anemia and asthenia are quite prominent after the second or third week of the disease.

DIAGNOSIS

The diagnosis of pyelitis is at times easy and at times difficult. It is often confused with typhoid fever. Our patient had a leucopenia and a mildly positive Widal suggesting enteric fever. However, leucocytosis is the more constant finding in pyelitis, and the pulse is rapid in contradistinction to typhoid fever. Malaria, especially in malarial districts and seasons, is often confused with pyelitis because of periodical chills and fever, but the absence of plasmodia, and the blood picture should clarify the diagnosis. The positive finding of pus cells in addition to the symptomatology described is sufficient clinical criterion for diagnosis. It may be possible that a twenty-four hour specimen will fail to reveal pus cells or pyuria, owing to ureteral blockage, and the urine will appear perfectly clear. However, repeated examinations will show pus urine or macroscopic blood as in our case which for eight weeks showed bloody urine to the naked eye. The long tailed cylindrical renal cells at one time retained as diagnostic of pyelitis are no longer of value, as cystitis may coexist with inflammations of the upper genitourinary tract. When hyaline or granular casts and erythrocytes are present in the urine, the diagnosis is usually that of pyelonephritis. The urine is usually acid except in staphylococcic, streptococcic, or pyocyanic inflammations.

The modern diagnostic methods include double catheterization of ureters with separate collection of specimens; pyelography and the finding of the specific organism, both culturally and by animal inoculation.

The x ray often reveals the presence of pyelitis by the annihilation of the characteristic angulations of the injected calyces and papillæ. Difference in postures may show ureteral kinking but will not affect the angulated appearance of the normal pelvis. Doubtless pyelography has come to stay.

Cystoscopy is valuable as revealing the coexistence of cystitis, the presence or absence of calculi, blockage due to structure or external pressure of the ureters.

TREATMENT

The treatment of pyelitis depends largely on the requirements of the individual case. The alkaline treatment, consisting chiefly of the administration of potassium citrate, especially in the early febrile stages of the disease, is according to many clinicians the most satisfactory method together with supportive and eliminative measures. Of the urinary antiseptics massive doses of hexamethylenamine (gr. fifteen every four hours) in combination with acid sodium phosphate (one half dram every four hours) has given satisfactory results in some hands, the formaldehyde being liberated in acid medium. Hexalresorcinal has of late come to the front. Leonard advises that its use be preceded by the administration of alkalies.

Autogenous vaccines have also been used. Urologists use pelvic lavages, with one per cent. silver nitrate, or mercurochrome. In our experience such lavages have been followed by a remission of fever and general improvement. The use of mercuro-

chrome is sometimes followed by chills. When the anemia is severe blood transfusion is indicated. Our patient showed most remarkable improvement after transfusion. Transfused blood is a most potent diuretic possibly by increasing the nourishment of the renal excreting cells.

CASE REPORT

CASE.—Mrs. A. C., aged twenty-five years, Italian, housewife, weight one hundred and ten pounds, height five feet two inches, about November 15, 1925, or a month preceding admission to the Methodist Episcopal Hospital, began to complain of headache, fever, edema of face and ankles; scanty and bloody urine. The following week digestive and respiratory symptoms supervened. Epigastric distress was followed by vomiting. Milk and liquids could not be retained. An unproductive cough and a sense of thoracic constriction were other complaints. Eleven days after the incidence of her illness she had one chill. In the third and fourth weeks there was a general subsidence of all symptoms but the urine remained bloody, abundant and with a thick sediment. At no time did she complain of dyspnea, hemoptysis, hematemesis, enterorrhagia. Menstruation, however, occurred twice in twenty-eight days and was rather scanty. There was occasional complaint of dysuria, urgency and frequency of urination.

Menstruation was usually regular, five days, occurred every twenty-eight days, flow moderate, no clots. One pregnancy, one child, no miscarriage. Dysmenorrhea before marriage. During labor eight months ago patient was "blind and deaf" for five days; probably due to eclampsia.

Had measles during infancy, and frequent attacks of colds. No other disease was remembered. No scarlet fever. Home conditions were hygienic and congenial. Did housework. Meals were regular; no alcohol or highly seasoned foods were used.

On admission to the Methodist Episcopal Hospital on December 16, 1925, patient was much emaciated, anemic, and dyspneic. Eyelids were slightly puffed up. No edema of the ankles. She had an impairment of the right base which cleared up in five days. The heart showed no enlargement or displacement but a soft systolic murmur was heard at the apex. P^2 more accentuated than A^2.

Liver not enlarged, spleen not palpable, kidneys *in situ*. No masses, tenderness, or rigidity present. The extremities were negative for edema and reflex abnormality.

Gynecological examination showed the uterus small, anteflexed, no masses on either side, slight erosion of mucous membrane, vaginal wall soft and pliable.

Laboratory findings (December 22, 1925): Hemoglobin 45 per cent., red blood cells 3,000,000, white blood cells 4,750, blood coagulation time three minutes. Blood sugar 0.112, blood urea 12.5 mgs., blood Wassermann negative. Phenolsulphonephthalein first specimen volume = 130 c.c. 10 per cent., second specimen volume urine = 70 cc.c. 10 per cent. Volume of urine 2.650 c.c. Albumin 0.45 per cent., 1.92 grms. 2,650 c.c. Urine cultures showed Bacillus coli negative for Bacillus typhosus. Blood Widal was negative for typhoid, paratyphoid A and paratyphoid B. Blood culture negative.

Right and left tonsil cultures showed many non-hemolytic streptococci, pneumococci and a few normal mouth organisms. Some pericementitis about the upper right molar which was carrying the bridge. No abscesses present and no root absorptions.

Blood count January 2, 1926, hemoglobin 30 per cent., red blood cells 1,100,000, white blood cells 7,650.

On January 9th patient underwent a blood transfusion operation receiving 416 c.c. of blood from her typed sister. Following the transfusion the patient had a marked chill but on the next day her improvement was remarkable. Her general appearance and color seemed to have improved like magic.

On January 13th, blood count hemoglobin 44 per cent., red blood cells 1,100,000, white blood cells 5,800, polymorphonuclears 73 per cent., small lymphocytes 20 per cent., large lymphocytes 14 per cent., mononuclears 2 per cent., transitionals 1, eosinophiles 0.

On January 21, 1926, her hemoglobin had ascended to 44 per cent., red blood cells 1,950,000, and white blood cells 5,700.

On January 13th the patient was cystoscoped with the following findings: Intense pallor of mucous membrane of bladder. Neither ureteral orifice showed any evidence of old hemorrhage. No obstruction to ureteral catheters—kidney reflex normal. Passage of ureteral catheters not followed by hemorrhage. Specimen of right and left urine sent to laboratory for culture routine and injection of guineapig. Cultures of both right and left urines were negative.

Routine of right: Color lemon: translucent-clear; reaction neutral; specific gravity q.n.s.; albumin cloud; sugar none; epithelial cells renal three plus; leucocytes few; red blood cells two plus.

Routine of left: Color lemon; translucent-clear; reaction neutral; specific gravity q.n.s.; albumin cloud; sugar none; epithelial cells renal; leucocytes few; red blood cells two plus.

From December 16, 1925, to January 14th temperature had been of the irregular septic type, oscillating between 98° F. and 101° F. Before admission temperature had followed practically the same curve.

Repeated urine examinations for four weeks following admission showed macroscopic blood. Trace of albumin, hyaline, granular casts, renal epithelial cells and urates for one week with many pus cells. Previous to her admission the patient had persistent bloody urine.

Since January 14, 1926 the patient's temperature has been normal with an occasional flare up of 1° or less. Hematuria macroscopic and microscopic have disappeared completely. The treatment followed has been the alkaline as outlined above, with daily injections of iron citrate and general supportive treatment.

This case represents pyelonephritis with hematuria persisting for two months. Subsequent urine analyses have been practically negative. Patient has steadily improved in weight, color and strength. Her blood pressure which was 160 over 110 in second week of the disease became 130 over 90 after two months' treatment, coinciding with subsidence of fever, clearing of urine and general well being.

An Unusual Case of Fibroadenoma of the Breast

MICHAEL W. BULMAN, M.D., M.S.Lond., F.R.C.S.Eng.
Norwich, England

The following case presents several features of interest and offers scope for speculation on the primary pathological lesion.

Case.—The patient, a married woman aged fifty-five, was sent to me on account of a swelling in the right breast. She told me she had had trouble with that breast for thirty-two years, ever since the birth of her first child. She was unable to suckle the child with that breast, as the milk did not agree with the child. She was told at that time that the breast engorged, but at no time as far as she could remember was it obviously inflamed and it certainly was never lanced: nor was any abscess present. From that time onward she had had an intermittent discharge of pus from the nipple, which prevented her feeding her seven subsequent children at that breast. She was certain that she had never noticed any lump in that breast until about two months before consulting me and at that time she discovered a lump about the size of a hazel nut. This lump became gradually larger for about five weeks and then increased rapidly in size till at the time she consulted me it was the size of a hen's egg.

The mass on examination was found to be in the upper and outer quadrant of the right breast, was of hard consistency and could be palpated with the flat hand. It was adherent to the reddened, inflamed overlying skin but was not adherent to the underlying pectoral muscles. The nipple was retracted. No glands could be felt in the axilla.

In view of the hardness of the tumor, the retroaction of the nipple and the age of the patient, a rapidly growing carcinoma seemed the most likely diagnosis. Nevertheless, the long history of discharge from the nipple and the obvious inflammation of the overlying skin made one wonder if a chronic inflammatory condition could suddenly have flared up.

At the operation an incision was made into the tumor and thick pus at once welled out. The surrounding tissue still felt so densely hard as to be suspicious of carcinoma and the complete operation was decided on, and after changing gloves and instruments the axillary glands and fat, the breast and both pectoral muscles were removed. No enlarged glands were found in the axilla, but on incising the specimen after its removal, its color, consistency and the way in which it appeared to be infiltrating a part of the surrounding tissue all seemed to support the diagnosis of carcinoma. A part of the growth was definitely encapsulated, but no capsule could be distinguished over the remainder. In some areas an appearance as of hyaline degeneration was presented. Culture of the pus gave a pure growth of Staphylococcus aureus, and that it remained still virulent after its long incarceration in the breast was shown by the fact that the wound suppurated in the area from which the growth had been removed and in no other part. This localized suppuration delayed healing for about a fortnight, but in all other ways convalescence was quite uneventful.

It is worthy of note that since the operation the patient has had no recurrence of the indigestion by which she had also been troubled for many years prior to the operation.

The following pathological report has been supplied to me by Dr. D. S. Brough: "The breast showed a definite tumor about the size of a hen's egg. On section the growth was seen to possess a fairly well marked capsule, was firm in consistence, and to the touch rather suggested a scirrhous carcinoma. Paraffin sections stained with hematin and eosine showed no evidence of carcinoma. The growth appeared to be an adenofibroma with a considerable amount of stroma. At one edge of the growth there was evidence of both acute and chronic inflammatory change, much round celled infiltration being present in some parts while in others polymorphous leucocytes were prominent."

There is, then, in this case a clear cut history of infection which had been present in the breast for thirty-two years and had remained active during that time, as evidenced by the frequent occurrence of discharge from the nipple. No lump had been present for more than three months, as far as the patient was aware, and it is probable that the attention given to the breast as a result of the discharge would have brought to light at an earlier date any but the smallest lump.

Has the fibroadenoma developed in consequence of the infection, has it developed merely in association with the infection, or has the infection settled in a preexisting fibroadenoma which acted in the breast as a *locus minoris resistentiæ?* To these questions I can give no definite reply. It seems unlikely that the fibroadenoma could have existed for thirty-two years without being noticed, for during that time it ordinarily would have grown to a very considerable size. Furthermore, the very definite history that after the discovery of the lump it grew slowly for some weeks and then suddenly grew rapidly suggests far more that the fibroadenoma became infected suddenly by the preexisting infection. In only three out of one hundred cases of hard fibroadenoma observed by Bryant (1) was the tumor first discovered after the age of fifty. Further, "it is probable that nearly all fibroadenomas arise between the age of puberty and thirty years," so that if this statement is true of this case it is still of interest that the condition should remain quiescent for so long a time.

While it is as yet too short a time since the operation for one to assert that the indigestion was permanently cured, it would appear that there has been a fairly definite relationship between this and the chronic infection. Certain forms of chronic infection, notably dental, are now well recognized as being causative of gastric symptoms, and there seems no reason why in this case these latter should not be attributed to the chronic intoxication.

Curiously enough, in this case the patient gave no history of trauma as a reason for the development of the lump and no scientific cause for the sudden flareup of the infection is obvious. Might it not be that the socalled trauma came from within the breast and consisted of the dislocation of the breast tissues resulting from the growth of the tumor?

I have been unable to find in the literature a report of a parallel case and put this case on record partly for its intrinsic interest and partly because it shows that even exploratory incision of a tumor is not always adequate to enable one to negative a diagnosis of carcinoma.

Plastic Surgery of the Nose*

A. G. BETTMAN, M.D.

Portland, Oregon

(*Concluded from page* 421)

The amount of material at hand is much greater than when rib cartilage is used. To build up the nasal bridge and glabellar region in one patient it was necessary to use seven pieces of celluloid one tenth of an inch thick and having a combined surface area of approximately five square inches. It would have been rather difficult to obtain so much rib cartilage from a patient.

The usual procedure to build up a nose has been to make a transverse incision in the glabella, pass an instrument down the anterior border of the nose, insert the properly shaped support from above and then close the wound with one or two sutures. This operation was done with cartilage by another surgeon to the patient represented in the illustrations.

The operation which I prefer is as follows: An incision is made on the inner surface of the ala on either side just within the nostril. A piece of fine silk is then passed through the edge of each flap and tied loosely so as not to produce pressure on the edges. These long sutures are used as retractors, thereby reducing trauma to a minimum and practically bringing the incision outside of the nasal cavity. The incision is deepened forwards until it reaches the anterior surface of the cartilage under the skin and adherent tissues. Through this incision all further procedures are carried on. With the dissector the superficial tissues are separated from the nasal cartilage and the nasal bone as far as indicated, being sure that the dissection is carried well down to the tip of the nose on both sides. For this purpose a dissector bent at right angles is used. When necessary portions of the laterally displaced nasal bones are removed with a spokeshave or chisel.

The properly shaped celluloid which has been prepared before starting the above steps of the operation is then passed up into place through the original incision. Should the celluloid when placed in position be found to be too large it is withdrawn, reshaped and replaced. Before placing the cartilage in position two silk or linen sutures may be attached to it one at either end. These sutures are passed out through the skin beyond the upper and lower ends of the graft and aid in placing it properly, and are tied over bits of gauze. These hold the graft in its proper position and prevent shifting which may take place if not guarded against.

*Read before the Portland City and County Medical Society.

When cartilage is used it may be obtained from the eighth rib on the right side or from the sixth or seventh. Some surgeons prefer to use that from the left side but most operators select the right as not being so near the heart.

When the celluloid is in its place the retraction sutures are removed and the mucous membrane closed with two or three horsehair stitches. A small piece of gauze held in place over the graft, with adhesive plaster, is all the dressing required.

It often happens that at the time of the accident producing the deformity other injury is done and when this is the case it must be corrected also. In the patient represented by Figs. 3 and 4 the left ala was torn from its support to the lip and when healing had taken place the left nostril was three sixteenths inch wider than the right. This was corrected by excising an elliptical section from the upper lip within the left nostril including the scar, separating the tissues well from the upper maxilla and suturing.

The alæ were thick as was also the columna and these were later reduced in size by excising elliptical sections, separating the underlying tissues well and suturing.

It is important that a second operation be not undertaken until the previous procedure has entirely healed else infection supervene. It is also important that an attempt be not made to do too much work at one time, lest the vitality of the tissues be impaired.

A certain amount of judgment as to the artistic must be possessed by the surgeon so that when the work is completed the nose reconstructed will be in keeping with the other features.

Some time ago a young man applied for treatment of his nose. The deformity consisted of an angulation of the lower portion. My judgment was that the proper correction consisted of lining up the lower portion of the nose with the upper giving a straight nose properly placed on the face. The patient desired that I remove the prominence of the angulation and thus apparently straighten the nose but producing a result so that the nose in its entirety would appear as if placed at an angle on the face. As the patient insisted on having the operation which I considered inadvisable and incorrect, operation was refused. One must be on their guard about following the advice of patients but must consider well from the standpoint of ultimate results. It may be the pa-

tient's nose in the beginning but it is your handiwork when the task is completed.

The shortened upturned nose is an interesting deformity. This may be the result of saddle nose or due to a short bridge. The condition may be congenital or due to faulty development, or the result of trauma. These noses vary as to the degree of disfigurement and as in all plastic work the treatment must be fitted to the conditions present.

When the lower border of the nose is tipped far upwards, that is, when the anterior border of the nose is much shortened, it may be necessary to supply a framework as described but a great many patients do not require this. The aim of the corrective procedures being to advance the tip of the nose and bring it down together with its adjacent lower alar border, several methods varying in detail are available.

When the deformity is small an inverted V incision may be made over the nose, the apex high on the bridge and the limbs ending near the nasolabial junction on either side. The under tissues are then well separated and the incision is sutured in the shape of the letter Y inverted.

In another one of my patients a different method was found necessary. The patient had a piece of rib cartilage inserted in her nose by another surgeon, the incision being made transversely in the glabella. The scar of the incision would have been less conspicuous had it been made longitudinally. This cartilage undoubtedly raised the bridge of the nose but was insufficient to remove the pug effect.

I operated as follows: An inverted V incision was made on each side of the nose the base extending from near the tip to near the junction of the ala and the cheek. The incision then extended onto the cheek. The issues were well undercut. The V was sutured as a Y inverted, forcing the tip of the nose downwards.

I wish now to discuss a class of cases which come infrequently to the surgeon for operation for reason that the deformity is very slight and most individuals would not consider it of sufficient importance to have corrected. I refer to that kind of nose in which the columna is low, extending onto the lip shortening it. In this type of case an inverted V incision is made on the under surface of the nose, the apex near the tip and the base along the nasolabial junction. The underlying tissues are separated and a portion removed, the wound being sutured as an inverted Y with horsehair. No dressing is required. The result was highly satisfactory to one of my patients, and while the difference was slight it was enough to give a much better appearance to her face. The lip was lengthened one tenth of an inch.

A nose whose tip hangs low over the lip may be brought up in either of two ways. When the cartilage extends low it must be excised preferably through an incision in the mucous membrane. When the drooping is low, due to relaxation of the soft tissues, these may be excised by making a double inverted V incision, the apices near the glabella and the limbs on each side meeting at the nasolabial fold. After removing sufficient tissue, careful suturing will produce a practically invisible scar. Remove the sutures early.

One of the commonest nasal deformities is that of the humped or round shouldered nose. The location and degree of the deformity varies. It may be the cartilage alone that is enlarged or the nasal bone, but usually both are involved in varying degrees.

In one type of cases the protuberance is chiefly of the nasal bone shading into the cartilage. The second involves both nasal bone and the cartilage. Both are operated in the same manner varying the amount of tissue to be removed to meet the case. Formerly a longitudinal incision was made along the anterior border of the nose. Soft structures were separated down to the bone and cartilage and the periosteum and perichondrium were then separated and retracted. With a fine saw, chisels and a gouge the required amount of bone was removed and the scalpel reduced the cartilage to the desired size and shape. The periosteum and perichondrium were replaced as were the overlying tissues and the skin was carefully reunited. A preferable method of operating is by making an incision inside the nostril along the anterior border, just above the mucocutaneous junction and continuing up through the ala until the anterior border of the cartilage is reached. The dissection is then continued, separating the nasal bone and cartilage from the overlying tissues for a sufficient distance above, below and on both sides to give space in which to work. A spokeshave is then introduced and the excess bone and cartilage removed. When necessary a chisel may be used.

The case represented by illustrations was more complicated. This young woman was thrown through the windshield of an automobile resulting in a hump on her nose and other deformities. An attempt was made to repair the damage. When I first saw her her nostrils were very small and there was loss of cartilage about the point of the nose. At operation the hump was removed, the nostrils opened, and the tissues rearranged so as to produce a satisfactory nose.

The hump was removed as heretofore described. Enlarging the nostrils was more difficult. The mucous membrane at the anterior tip of the nostril was cut sagittally, separated well back and the wound sutured in the opposite direction. This gave about four times the capacity to the nostrils but they were not yet large enough. Later an incision was made in the mucous membrane, the skin and mucous membrane were well undercut, a small portion of cartilage removed and sutures placed so as to close the wound with the desired result.

A woman who had a large, deep, prominent and unsightly scar on the bridge of her nose asked to have it removed. To do this there was excised from the bridge of her nose an ellipse of skin which measured five sixteenth inch wide by eleven sixteenth inch long. Undercutting and careful suturing with horsehair gave a perfect result.

A young woman asked for relief from an unusual condition. As a result of muscular action in drawing the nose over to one side when speaking her nose was deviated so that the tip pointed decidedly to the right. An ellipse of skin, its centre at the anterior angle of the nostril where the skin and mucous membrane join was excised and a triangle of cartilage with it large enough, so that the nose was slightly overcorrected. The scar was invisible and the correction complete.

Another condition of which I will speak is probably the most interesting. It is the deformity of the nose which occurs with cleft lip. The cleft side of the nose is flattened, the ala is broadened and the nostril is otherwise out of shape. The present patient had a complete cleft lip and cleft palate which were partially operated upon when he was about a year old and the alveolar process and the lip were united. I operated for the closure of the palate defect and later the nose was operated on and the lip deformity corrected.

The nasal part of the operation was done as follows: Sufficient tissue was removed from the portion of the lip entering the nostrils to bring the ala into proper position, the nostril being well undercut. The edges were sutured with horsehair. A longitudinal incision was made almost the entire length of the columna, curved toward the left at the lip and to the right at the tip. The incision was sutured so as to bring the left half of the nose into normal position. Silkworm and horsehair were used.

CONCLUSIONS

In conclusion, I would repeat only two things: Treat the tissues kindly.

Forget about approximating wound edges but bring the edges of the wounds into exact apposition.

407 PARK BUILDING.

Macrosomia or Congenital Hypertrophy

E. D. FENNER, M.D.

New Orleans, La.

Macrosomia, or gigantism, has been defined as "a monstrous largeness of the body." The entire body may be involved, and in this case there is no disturbance of symmetry other than excessive size; the condition may affect one lateral half of the body, when it is usually spoken of as congenital hemihypertrophy; or it may be confined to a single member, or part of a member. Instances of the latter class are naturally more frequent. Whether total or partial, the essential features of the condition are that it is congenital; that all the tissues, skin, subcutaneous fat, muscles, and bone, are involved; and that, in truth, we know nothing about its causation. This does not mean that numerous speculations have not been advanced to account for it, but that none of these are really satisfactory in explaining the overgrowth.

Heredity, maternal impressions and injuries, syphilis, alcoholism, have all been given a place in the etiology, but the connection of any one of them with the hypertrophy has not been satisfactorily established. Polosson believed that macrosomia was due to a disturbance in the lymphatic system which bore a resemblance to elephantiasis. Barwell invoked a failure of development in the muscular tunic of the arteries to explain the overgrowth of the tissues irrigated by them. Trelat and Monod concurred in this view, pointing out the analogy existing between congenital hypertrophy and the nutritive changes seen in arteriovenous aneurysms. Duply advanced the view that the cause was a trophic disturbance of nervous origin. The endocrine system has not been forgotten by those who have sought to explain the occurrence of congenital hypertrophy. It must be said, however, that pathological anatomy lends no support to any of these theories, and that the etiology remains a mystery. It should be noted, however, that vascular nevi are frequently encountered in the affected parts. Macrosomia is stated to be more frequent in boys than in girls, and on the right than on the left side.

The symptomatology consists chiefly in the enlargement of the parts. The discrepancy in size is noticeable at birth, or very soon thereafter, and becomes more striking as age advances. Where both upper and lower limbs are involved the hypertrophy is always more decided in the lower than in the upper limb; and where the whole lower extremity participates in the hypertrophy the leg is apt to be relatively longer than the thigh. In a few cases, the viscera have been found to be enlarged on the affected side as well as the limbs. Reference has already been made to the frequency of vascular nevi in the parts affected. Moreover, the coexistence of other disorders of development, such as syndactylism, has been noted. The skin may be smooth and clean, but not infrequently it is thickened, indurated, and resembles that of elephantiasis. Occasionally there is a greater development of hair over the affected regions. The only other symptoms are such as are a natural result of the greater size and length of the parts. The general health and intelligence are not impaired.

The history of my case is as follows:

Case.—Tillie D., seven years old, was admitted to my service at the Charity Hospital in the early part of June, 1921, on account of a swelling over the lower half of the left tibia, which followed a blow received two months before, which had increased rapidly in size. The father, mother, one sister, and three brothers were living and well. There was no history of tuberculosis, malignancy, hemophilia, or syphilis in the family. The child was born at term, and was normal except for some enlargement of the left leg and thigh. She was breast fed until fifteen months old, and was then gradually put on table food. She had had no infantile diseases, and no sickness except influenza during the epidemic of 1918. As she advanced in age the hypertrophy of the left lower extremity became more and more noticeable, but no treatment was considered until the swelling over the lower half of the left tibia developed after a contusion received on April 10, 1921.

She was well developed and well nourished; skin was smooth, moist, with no scars, and no eruption. Pupils were equal and reacted to light and accommodation; there was slight ptosis of the left lid. Mouth and teeth were in poor condition; tonsils showed mod-

erate hypertrophy. Heart and lungs were normal, and the abdomen negative. The upper limbs were normal. The left lower limb was about five inches longer than the right and about twice as large. The disparity was greater below the knee. Muscles were flabby and the skin rough and coarse. The left labium majorum

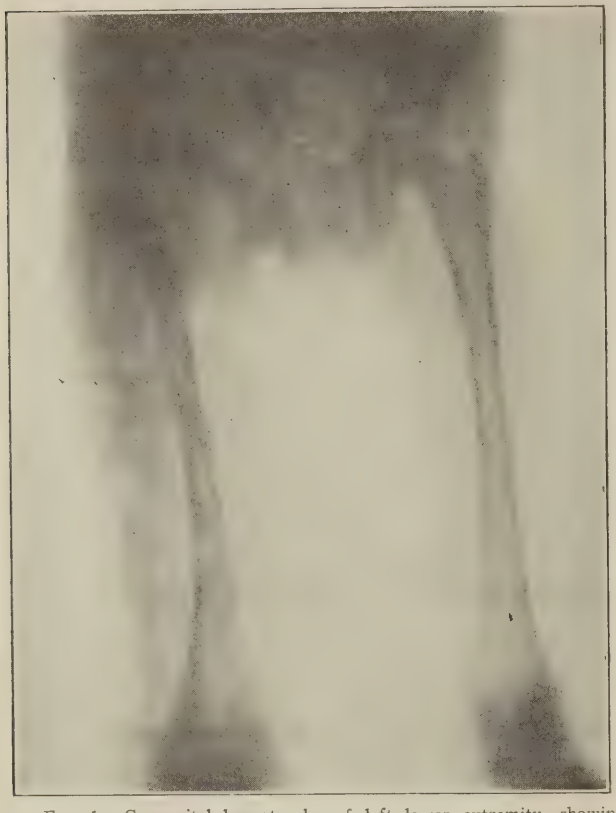

Fig. 1.—Congenital hypertrophy of left lower extremity, showing overgrowth of thigh and presence of a decided coxa valga.

was markedly hypertrophied. There was decided genu valgum, probably compensatory. Over the lower half of the left tibia there was a large soft swelling attached to the bone. This was not painful or tender, but had been increasing rapidly in size. There was no enlargement of the lymphatic glands, and reflexes were normal.

Laboratory findings showed negative Wassermann reaction. Total leucocyte count 8500; erythrocytes 4,750,000; hemoglobin 85 per cent; color index, 92; differential count: small mononuclears 21 per cent; large mononuclears 8 per cent; neutrophiles 68 per cent; eosinophiles, 3 per cent; no pathological changes in red cell; no plasmodia; urine normal.

On June 15th, excellent skiagraphs showed gigantism of the entire skeleton of the left lower extremity. There was evidence of a chronic low grade periostitis of the left tibia. At the hip there was coxa valga. The shadow of a tumor connected with the tibia and invading the soft parts was plainly shown in the lower part of the leg. An exploratory incision was made over the tumor, and a piece sent for examination was reported to be undoubtedly fibrosarcoma.

The interest of this case is enhanced by the presence of decided knock knee and a remarkable degree of coxa valga, but still more by the development in the hypertrophied limb of a rapidly growing fibrosarcoma, following a simple contusion received two months ago. So far as the congenital hypertrophy was concerned no treatment appeared to be indicated, unless the use of a high shoe on the other limb, or possibly, after the age of adolescence, an effort to shorten the limb by a resection of a portion of the femur and the bones of the leg. The sarcoma rendered treatment urgent. The parents finally gave their consent to amputation.

The argument in favor of amputation was based upon the following considerations: Excision of the tumor bearing tissues would necessitate the removal of the greater part of the shaft of the tibia, together with a good deal of the soft tissues. Simple excision carried the threat of early recurrence, and even if this did not occur a secondary operation of bone grafting to restore the tibial shaft would be needed. Even if there were no recurrence, and a secondary grafting operation were successful, the child would be left with a limb five inches longer than its fellow, and would still be a cripple.

A transcondyloid amputation seemed to me a better operation than one through the knee joint as it promised by the removal of the lower epiphysis of the femur to prevent the continued outstripping of the normal limb in length, and would permit the fitting of an artificial limb with the knee joint on the same level as in the sound limb. The operation was accordingly carried out as planned. Healing was delayed by an obstinate watery discharge from the

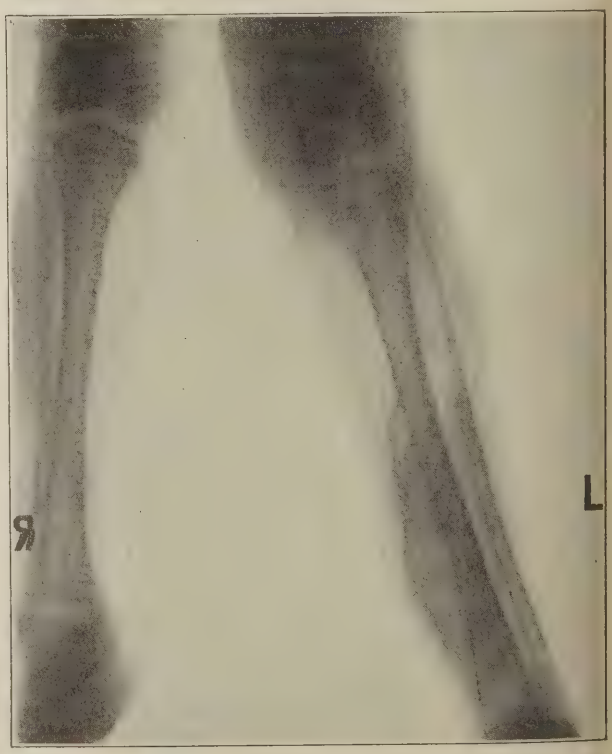

Fig. 2.—Congenital hypertrophy of left lower extremity, showing presence of a fibrosarcoma of left tibia, resulting from a blow two and a half months ago.

stump, but ultimately the amputation wound healed and the patient was discharged.

In spite of many efforts it has been impossible to get any information as to the subsequent history, and we do not know whether metastasis occurred, or whether the child is still living.

1810 St. Charles Avenue.

A Contribution to the Efficacy of Ether in the Treatment of Suppurative Otitis Media

GEORGE B. McAULIFFE, M.D.

New York

I cannot recall to whom credit is due for suggesting the use of ether in the treatment of purulent otitis media. I know, by personal experience, that it is a remarkable and simple method of curing tympanic suppuration. Its simplicity makes it easy for administration at home. It serves as a differential diagnosis between tympanic and mastoid discharge because in the cases in which it failed to relieve, x ray examination has revealed a chronic mastoiditis. It finds its best use in old cases where the perforation is large enough to allow entrance of the ether into the tympanum. Naturally, when the small size of the perforation precludes the probability of the entrance of ether, we cannot expect results. In acute cases my experience has not been sufficient as yet to merit advocacy of the remedy to shorten the attack. I have found it practically unirritating. Children as well as adults do not often complain after the first administration by the nurse. In the Cornell Clinic I took a series of about seventy-five cases of all kinds of discharging ears—a short résumé of some of the cases follows:

Case I.—J. M., had discharging ears from measles in childhood. On September 30, 1925, her ears began to discharge again. Ether was used twice a day. October 7th found the left ear dry; right ear discharging. October 22nd, both ears were dry. There were small perforations. On November 9th ears were still dry.

Case II.—B. L., had discharging ears for two years. On October 16th employed ether; on the 30th, the discharge had ceased.

Case III.—L. H., left ear discharging for seven months; right ear for two months. After one treatment of ether the discharge stopped. A week later it was still dry.

Case IV.—T. S., had discharge for ten years. October 24th ether was used and twice a day thereafter. Discharge stopped one week later.

Case V.—E. R., had discharging ears for a few days. One application stopped the discharge.

Case VI.—V. W., had discharge from ears for six weeks. It stopped after one month's treatment.

Case VII.—A. B., on September 22nd, had pain for two days; seropurulent discharge followed. On September 29th ether was used, and on October 8th the discharge stopped.

Case VIII.—D. O'C., had had running ears for years. On October 16th ether was administered, and on October 23rd the discharge stopped. On October 30th the ears were still dry.

Case IX.—J. G., had had discharge from his ears off and on for years. On September 23rd ether was used and on September 29th the discharge stopped.

Case X.—M. C., sixteen years old, had had chronic otitis media purulenta for eight years in right ear. On October 28th ether used and the discharge stopped in two weeks.

Case XI.—E. H., twenty-one years old, had discharge from ear for four days. It had discharged off and on for years. On October 27th ether treatment was begun; discharge stopped on November 4th.

Case XII.—T. G., ten months old, had double purulent otitis media for ten days. On October 21st ether was used. Discharge stopped in two days.

Case XIII.—E. Z., aged twenty-five years, discharge from right ear for seven years; thickened membrane with central perforations. On July 29th ether was begun, and on September 1st discharge stopped.

Case XIV.—J. M., aged sixteen years, had had a discharge from his right ear since he was nineteen months old. He had had all kinds of treatment. He has an open ear with polypoid growth from the attic. On July 9th ether treatment was begun. On September 9th there had been no results. X ray showed a sclerotic chronic mastoiditis, and an operation was advised.

Case XV.—E. N., seventeen years old, right ear discharging thirteen years after mastoidectomy; ossicles skeletonized. Used insufflations of boric acid powder for two months. August 4th ether treatment was begun. On September 22nd there was no discharge. On October 6th the ear began to discharge again; ether was resumed and the discharge stopped in a week.

Case XVI.—O. H., nine years old, had had intermittent discharge since he was three years old. Right ear had been discharging now for three weeks. He had had a mastoidectomy done on left side seven years before. July 29th ether treatment was begun. On August 19th the ear was dry. On September 23rd the ear was still dry and hearing almost normal.

Contrary to the suggestion first given by the originator of the treatment who said the ear should be washed only the first time before the treatment was instituted, I have the ears thoroughly cleansed by a boric acid irrigation, partially dried and then with the affected ear uppermost fill the canal with ether. The patient remains in that position until the ether has evaporated. This treatment is given twice a day. Ether boils at 95° so it gives the patient the same sensation as peroxide of hydrogen. It is an easy method for home treatment where syringing at best is not always of one hundred per cent. efficiency.

Naturally one is curious to learn the rationale of its effect. I wrote to Dr. James Ewing for an explanation. He said, "I am quite unable to give you any information regarding the effects of ether on pus. I have never heard of it being used in this relation. I should think it might be a fairly active and effective cleanser; moderately bactericidal, and possibly it might stimulate normal healing."

Dr. Fenton Turck said: "The effect of chloroform, alcohol, ether on cells of the organism was worked out by me in 1903. It indicated that the effect of any

of these anesthetics was to cause an escape of the cell contents which were found in the blood. In prolonged use it seemed to cause the phenomena of shock; in shorter periods of time it seemed to act as a stimulus. The stimulus, therefore, was not the agent but the product of the cells which was released by these agents. The use of ether in the ear would seem to be justified on a biological basis."

In the late war ether was used by the French in gunshot wounds with benefit.

In the *Handbook of Antiseptics* (Dakin and Dunham) Topley is quoted as saying, "that the vapor of ether has a slight but definite bactericidal action. It takes one to forty-eight hours to sterilize pyogenic organisms in agar slants. Ether is irregular in its action. It is clear that the benefit is not a direct disinfection of septic infection.

Waterhouse used ether since 1909 in the peritoneal cavity and in the bladder. In the peritoneal cavity he used three ounces of ether. He speaks very highly of its effect in the *British Medical Journal,* September 6, 1915.

In an examination of smears taken from the ear before and after treatment, the laboratory assistant at Cornell found that the bactericidal count diminished from 70 to 10. At present it is impossible to state what is its real action. Clinically it stops pus formation. Does it do that by its bactericidal action or by its action on the cells (Turck) or as this authority also states, by microscopic cauterization? The fact remains that it is, in the majority of cases, distinctly beneficial. Its effect is sometimes so quick that in one instance where a general practitioner had used it in the ear of a child, the mother came to the clinic alarmed that the discharge had ceased so quickly, fearing that some dangerous sequel might have occurred from the sudden stoppage of the ear discharge. I present the foregoing conclusions from a purely clinical standpoint.

26 West Eighty-seventh Street.

Ascites*

NORMAN C. PAINE, M.D.

Glendale, California

Ascites comes from the Greek word meaning bag. Usually the term means an accumulation of serous fluid in the peritoneal sac. Free fluid accumulations consist also of chyle, bile, or blood. There is normally a small amount of fluid in the peritoneal cavity changing constantly by absorption and further transudation. A lack of balance between these two, as imperfect absorption or increased transudation, will lead to excess.

Cabot (1) in analyzing 224 autopsies where ascites was present, found eighty-eight per cent. caused by, first, heart disease; second, kidney disease; third, hepatic cirrhosis; fourth, peritoneal tuberculosis, and fifth, abdominal neoplasms. Other causes for ascites are intestinal obstruction, pernicious anemia, leucemia, visceral syphilis, portal vein obstruction, mesenteric thrombosis, pericardial adhesions, perisplenitis, perihepatitis, ankylostomiasis and echinococcus. The abdominal tumors include ovarian cysts and tumors, uterine fibroids, peritoneal carcinoma, tumors of the kidney (sarcoma, hypernephroma, hydronephrosis) and hepatic carcinoma.

The symptoms in pathological accumulations are painless abdominal distention, sense of weight in the abdomen, dyspnea, anorexia, emaciation, constipation and often anuria. Objectively there is dullness on percussion in the flanks which shifts when the patient alters position. The abdominal skin is smooth and shining, the base of the thorax broadened and the navel obliterated. The fluctuation of fluid may be demonstrated when a hand is placed on one flank and tapping done on the opposite side with the other, an assistant's hand placed firmly and vertically in the midline to cut off the tissue wave. The fluid in passive congestion usually has a specific gravity under 1,020 and contain a few cells, whereas in inflammatory conditions the fluid contains many cells and has a specific gravity of over 1,030. When the fluid arises from carcinoma it may be of a dirty gray color, turbid or sanguineous, with many cells. It is doubtful if x ray examination is of any particular value in the diagnosis of small accumulations, for even moderate amounts of fluid may escape detection.

Diagnosis depends on the history, symptoms, physical examination and withdrawn fluid findings.

Differential diagnosis must be made from ovarian cysts and other abdominal cysts, distention of the bladder, obesity, tympanites, pregnancy, choleperitoneum, hemoperitoneum. The dullness in ovarian cysts is usually unilateral or over the central part of the abdomen with tympanites in the flanks. Cysts of kidneys, pancreas or liver are likely to be unilateral or occupy a part of the abdomen only with tympanites elsewhere. X ray examination is helpful in most of these cases. The catheter rules out bladder distention. With obesity there may be a suggestive succussion wave, but no dullness in the flanks. Tympanites should not be confused with ascites. In pregnancy an x ray examination is conclusive. Hemoperitoneum is usually an acute surgical affair characterized by faintness, pallor, dyspnea, restlessness, tachycardia, vomiting, and colicky pains. It follows ruptured extrauterine pregnancy, trauma to abdominal organs, as gunshot wound, rupture of spleen or liver, or mesenteric vessel, ruptured abdominal aneurysm, or varicose vein, or hemorrhage from carcinoma or sarcoma. Choleperitoneum and chylous ascites may only be diagnosed by puncture and examination of the fluid. The only choleperitoneum I ever saw was last October when I did not drain after a cholecystectomy and the stump of the cystic duct

*From Department of Internal Medicine service of Dr. John W. Shuman, Los Angeles General Hospital. Read at January Staff Meeting.

leaked. Drained on the ninth day the patient made an uneventful recovery. Chylous ascites is a rare condition in which the fluid is milklike. It may occur in tuberculosis, carcinoma of the peritoneum, cardiovascular conditions, rupture or obstruction of the large lymph vessels or receptaculum chyli, cysts and filaria.

The treatment of ascites, at least from the viewpoint of the patient, is the most important consideration. Rest is a great factor, especially in cardiac and renal cases. The restriction of fluids to two hundred c. c. and a maximum of eight hundred c. c. a day is advisable, with the preference given to milk or buttermilk rather than water. The Karrell diet of milk and zweiback four times a day, later adding eggs up to five or six a day, has proved valuable. This can then be increased to a soft diet, either salt free or salt poor. Weighing the patient daily helps to keep up his morale by demonstrating the weight loss, and occasionally it is necessary to interpose a few days of normal diet to relieve the monotony. Catharsis with the hydragogues may be of great value in the cardiac and renal cases. Jalap powder, elaterium and salines are valuable.

Recently we have tried ammonium chloride in large doses in conjunction with novasurol (2), which is a thirty-four per cent. mercurial introduced by Zieler (3) in 1917. (Novasurol is the double salt of sodium mercurichlorphenyl oxyacetate with diethylbarbituric acid—barbital.) This drug may be used intramuscularly or intravenously beginning with a .5 c. c. dose and running up to 2 c. c. Tolerance must first be determined in the smaller doses. Recent papers from the Mayo Clinic (2) report quite striking results with this drug in ascites of hepatic origin, and also in ascites and edema in nephritis. They used from three to seven doses at intervals of three days to a week. Four doses were usually sufficient. In our ward we have not duplicated their success. One case of long standing ascites of renal origin showed a remarkable improvement after the first week. Excretion jumped from three hundred c. c. to over two thousand c. c. in the first two days after novasurol was administered. Within three weeks, however, the ascites, which had diminished rapidly at first, returned. No amount of juggling with ammonium chloride and novasurol had any further effect on the ascites, though a diuresis of short duration followed each injection of the latter. In a second case a stomatitis developed and the patient was salivated after two doses of novasurol. Dr. E. L. Armstrong (4) reported some splendid results on his service though one patient with hydrothorax and ascites absorbed the ascitic fluid but was not relieved permanently of his thoracic transudate.

When the patient suffers from the presence of fluid abdominal paracentesis is indicated. It is done midway between the symphysis and umbilicus after the bladder has been evacuated. Large ascites are best drained slowly because sudden decrease has caused fatal stomach and bowel hemorrhages. We have recently seen a fatal peritonitis four days after abdominal paracentesis. Some patients live years and undergo numerous tappings. Persistent leakage through the puncture is not advisable because of the danger of infection.

Surgical measures have been advocated. The Ech fistula between the portal vein and the inferior vena cava has not been successfully performed on the human. But an anastomosis between a large mesenteric vessel and the iliac vein has been done. Talma (5) and Morison (6) independently in 1889 and 1896 devised the operation of omentopexy. This may be done simply by multiple suture points of the omentum to the parietal peritoneum, or better by drawing the omentum out and inserting it into pockets beneath the abdominal muscles. One statistician (7) finds thirty-three per cent. mortality, seventeen per cent. failure, thirteen per cent. improved, and thirty-seven per cent. cured. It is not a procedure to be recommended early.

The prognosis in ascites is not good. Fluid may remain in the peritoneal sac for years but when pronounced it prognoses death. It should be recognized early, carefully studied, and treated.

CASE REPORTS

Case I.—M. S., male, aged sixty-one, was admitted July 20, 1925, with a history of ascites for five months with two tappings. He had had high blood pressure for several years. On examination the blood pressure was found to be 230/150; urine contained albumin, hyaline and granular casts, phenolsulphonephthalein seven and a half per cent. first hour, and two per cent. second hour. Some improvement resulted from rest, restricted fluids and elaterium. On October 26th novasurol was given in .5 c. c. doses and excretion increased from 300 c. c. to 2,400 c. c. on October 29th. After four doses of novasurol at three day intervals, ascites was greatly reduced. After ten doses the ascites was the same as before treatment and paracentesis required. On December 16th the patient was discharged unimproved.

Case II.—F. A., male, aged thirty-two, was admitted December 1, 1925, with a history of dyspnea on exertion and generalized edema. On examination there was found systolic mitral murmur and slight albuminuria; phenolsulphonephthalein twenty-two per cent. first and forty per cent. second hour; there was edema of extremities. Patient improved rapidly but would not remain at rest. On December 11th a slight respiratory infection developed which was followed by more marked edema and ascites. Elimination, restricted fluids, and digitalis gave slight improvement. On January 1st one c. c. novasurol was administered. Within forty-eight hours salivation developed and marked stomatitis. Ammonium chloride was continued but novasurol was discontinued. Karrell diet now induces vomiting and must be discontinued. No improvement.

Experimental Investigations Into the Action of Salvarsan

JOSEF SCHUMACHER, M.D.

Berlin

(Translated by Edward Ahlswede, M.D., Hamburg)

The beginning of this century witnessed a series of important discoveries in research work on syphilis. Schaudinn and Hoffmann, von Wassermann and Ehrlich were the chief investigators. Although salvarsan did not fulfill the expectations of Ehrlich and, as I shall point out later, could not do what was expected of it in the advanced stages of the infection, the superiority of salvarsan over all the other antisyphilitic agents is now generally admitted. Ehrlich discovered a new and powerful weapon whereby every practitioner was enabled to help successfully in the fight against syphilis. It would, however, have been of equal importance in the early days if we had been better informed of the chemical reactions which take place between the spirochetes and salvarsan, and of the reactions which account for the action of the latter, aside from the general scientific interest of this question.

The majority of investigators in the early salvarsan era followed Ehrlich's footsteps, in the hope of finding by purely empirical experimentation, that is, by testing out numerous similiar compounds, one which would possibly prove superior to salvarsan.

As early as 1914 (the beginning of the following investigations dates back to this year), I attempted to explain by microchemical investigation those processes which lead both to a fixation of salvarsan in the body and in the parasite cell, as well as those which finally bring about the devitalization of the spirochetes. This I believed would possibly explain the mechanism of the action of salvarsan and be of some value also in the synthesis of other nonarsenical compounds for the cure of syphilis.

The purpose (1) I had in mind in those days and which I tried to reach by subsequent investigations, was summarized seven years ago, in my paper (2) as follows: "What chemical reaction with what atom groups of salvarsan, and what chemical substances in a particular anatomical site of the cell must take place in order to produce a spirillicide action? This is the main question. If we could definitely decide this question we would be able to determine exactly what chemical properties of a substance are required to develop an action similar to that of salvarsan, for instance.

We would then also be in a position to build up synthetically similar compounds, as we would know exactly what chemical composition guarantees a spirillicide action. In the search for new therapeutic agents we have hitherto worked mostly empirically, following Paul Ehrlich's example, and yet the other way, that is, the microchemical investigation of the action of the individual substances, is scientifically the more exact and promising, though the more tedious."

I did not feel justified in publishing the results of my investigations before all of these questions had been answered experimentally beyond all possibility of doubt. My first reports on the action of salvarsan were therefore made only one and a half years ago at the Munich Dermatological Congress (3). As early as 1916 I was convinced that the Spirocheta pallida was a microorganism poor in oxygen, as I will prove later. The action of salvarsan also seemed to be based on the oxygen abstracting power of arsenic, the effect of which could in all probability be increased by vanadium, an agent which for years has been known to be a still more powerful abstractor of oxygen. Unfortunately, lack of financial support prevented me from further experimentation in this direction. In the meantime, eight years later, vanadium has been tested empirically and its effect on syphilis has been recognized and reported by the American authors, Proescher, Seil and Stillians (4) and the Germans, Winkle (5) and Kroesl (6).

Numerous other problems remained unsolved in those days and even today, a few of which only may be mentioned here. It was of vital importance to know the chemical composition of the spirochete and why salvarsan, for instance, has no influence on spirochetes *in vitro,* yet a marked influence *in vivo.* Nor do we know the primary alteration products of salvarsan *in vivo.* Our knowledge on this point is limited to a few theoretical assumptions. The physical and chemical properties of these alteration products are also unknown. What chemical reaction do they produce in the living spirochete? What chemical reaction between what cellular substances of the Spirocheta pallida, on the one hand, and what salvarsan alteration compounds, on the other, occur in order to make possible a spirillicide action? What accounts for the spirillicide effect after the reaction has taken place? We were also unable to explain the optimum action of salvarsan on spirochetes as compared with the action of the other arsenicals prepared by Ehrlich. Do spirochetes possess an arsenoceptor in the sense of Ehrlich? If so, what substances represent it? Do spirochetes also possess an aminophenoloceptor and by what substances is this represented? Ehrlich assumed that salvarsan is primarily anchored to the parasite by the socalled o-aminophenoloceptor. He was encouraged in this assumption by the fact that arsenophenol is considerably strengthened in its spirocheticidal properties the moment amino groups assume the o-position to the hydroxyl group. In the further course of his investigations Ehrlich concluded that spirochetes possess an arsenoceptor, which, as he proved, is only tuned to arsenic with three and not with five valences.

These questions do not cover all the problems of interest in this connection. We would also want to know why arsenicals with three valences are so very effective and those with five valences so much less effective. Why do arsenobenzoles lose their effect as soon as carboxylization and sulphurization occurs? Why is salvarsan so weak in its antibacterial action? Clinical questions are also of interest. Why does the *sterilisatio magna completa* fail in so

many instances? Which of the numerous arsenicals is the more suitable for this purpose and why? Why does the abortive cure of syphilis succeed only in a certain percentage of cases and why is it not possible after a certain advanced stage of the infection?

These are only a few of the questions which require explanation, and their number could be easily doubled if we were to consider which of the salvarsan compounds is the most suitable and if we were to consider also the mode of action of mercury and bismuth as well as the correlation or possibly the antagonistic action of salvarsan and the metal compounds. It may be agreed that clinical experience alone cannot answer all of these questions satisfactorily. Practical experience in the last fourteen years has in fact proved this. Clinicians cannot answer these questions satisfactorily because they are still obliged to work with *two unknown quantities,* that is the unknown *chemical nature of the Spirocheta pallida* and the likewise unknown *alteration of salvarsan in vivo.* Nor can pharmacological investigation alone aid in the solution of the problem as it usually works with one unknown quantity, namely the chemical constitution of the parasite. It seems that microchemical investigation alone can furnish the final solution of the problem as it enables us to eliminate *both unknown quantities,* as I hope to prove by the following.

To understand the mode of action of salvarsan on the *living* spirochetes and body cells it is necessary to find out first what chemical reaction takes place between salvarsan and the *dead cell.* For didactic reasons these experiments are discussed first.

Salvarsan is fixed to the *dead cell* chiefly by the *nucleoproteids* as well as the *lipoproteids* (lipoid albumin compounds) of the cell protoplasm. This is proved by the observation that after the removal of nucleic acid from the nucleoproteids, for example, salvarsan can no longer be bound by these. The same negative results are obtained if the nuclei of leucocytes, for example, are dissolved with sodium carbonate and the latter are then treated with an ammoniated albargin or silver nitrate solution, to demonstrate the possible binding of salvarsan to the cell.[1]

In these instances certain ions of the alkali and earthy alkali metals play a certain part, as they hasten the precipitation of the salvarsan base. This will be referred to later. While a salvarsan nucleus picture, for instance, is not obtained after removal of the nucleic acid from the nucleoproteids of the leucocytes, the nuclei appearing as clear gaps, microorganisms, even then bind salvarsan. The latter possess, as it were, two "receptors" for salvarsan, in Ehrlich's sense. One is represented by the nucleic acid or nucleoproteids which they contain and the other by their content of lipoproteids. For the same reason salvarsan is fixed by spirochetes, that is, both by the Spirocheta pallida, free of nucleic acid, and the lipoproteid and nucleic acid containing buccal spirochetes.

While Ehrlich assumes that salvarsan is "anchored" to the cell by its individual haptophore groups, microchemical investigation shows that this is not the case. Chemically a *salt* is formed in these cases, namely nucleic acid salvarsan. The powerful reducing capacity of salvarsan is due to its reduxophore groups by which is meant the sum of the —OH and $—NH_2$ groups. If one of these groups is destroyed, as by diazotation of salvarsan, the powerful reducing capacity of salvarsan is lost, which proves that this powerful reducing capacity depends on the integrity of *both* groups. Furthermore, if the two phenylhydroxyl and arseno groups could account for this powerful reducing capacity they would have to develop this high power at this very stage. That is, however, not the case. The fact that a certain reducing power (though this is developed after a considerable lapse of time only) must be conceded to the arseno group is proved by the experiment with diazotated salvarsan and ammoniated silver nitrate solution, which latter also turns brown after twenty-four hours.

As an alteration occurs only in one of the two —OH or NH_2— groups, which also takes place in the event of a substitution) and as this would also occur if salvarsan was bound to the cell by one of these groups, unless a simple additional compound is formed (which is actually the case), and as furthermore the very powerful reducing capacity of salvarsan is still preserved after its fixation to the cell, it follows that neither the OH— nor the $—NH_2$ groups plays any part in the fixation of salvarsan to the cell. Nor does there exist an arsenoceptor in the sense of Ehrlich, by which the arseno groups might act as agents in the chemical reaction between salvarsan and the cell. If this was the case, salvarsan which has been treated with nucleic acid sodium *in vitro* could not react a second time with another nucleic acid molecule of a cell nucleus and furnish a histologic nucleus picture. Macrochemical peculiarities also point in this direction, as one can prove that nucleic acid salvarsan, which has been demonstrated microchemically, can also be obtained macrochemically, the latter still being subject to diazotation, that is still in the possession of an intact amino group. Dehring has also prepared nucleic acid salvarsan macrochemically.

Conditions are entirely different in the living cell. Yeast cells and other microorganisms, as well as spirochetes, show a similar response. Living yeast cells do not bind intact salvarsan, as can be shown by mixing these cells with an intact salvarsan solution and rendering them free of salvarsan in the centrifuge. The living cell, however, immediately binds salvarsan if the latter is oxidized by the passage of an air current.

The different biological response of spirochetes and bacteria to the action of salvarsan must logically be due to the different structure and constitution of these microorganisms. While one can prove that the Spirocheta pallida is poor in oxygen, the bacteria must, generally, be considered to be very rich in oxygen, like the body cells. At a certain concentration in the blood the oxygen poor spirochetes succumb to the oxygen abstracting action of arsenic at a time when

[1] The binding of salvarsan to the dead cell is demonstrated in the following way: Cell smears are fixed in heat and then held for 2-5 minutes in an aqueous solution of 1-1000 neosalvarsan and rinsed in water. A one per cent solution of albargin, to 100c.c. of which three drops of concentrated NH_3 are added, is then poured over the cell smear and the salvarsan picture developed (as in photography) by moving the glass slide to and fro. A leucocyte smear will then show that the nuclei, in particular, stain dark brown, less so the protoplasm. The former have therefore bound the larger amount of salvarsan. The other salvarsan pictures are prepared in a similar way. The neosalvarsan solution in the above is prepared with tap water.

the body cells, and even later the bacteria, have not yet been damaged to any similar extent. Chemically the spirochetes are reduced; biologically, they are suffocated before the body cell is affected by salvarsan, owing to its higher content of oxygen. If this oxygen abstracting capacity of arsenic is further increased by the introduction of powerful reducing groups into the particular arsenicals, compounds are obtained which are therapeutically more effective and therefore develop a more favorable therapeutic index. The latter is comparatively unfavorable with the p-oxy-m-aminophenylarsinoxide, while it is very favorable with salvarsan.

The increase in the spirillicide action which is effected by the additional oxygen abstracting process in the presence of reduxophore groups (as in salvarsan) as well as the decrease in this spirillicide action if the amino group is substituted (the reduxophore groups are then missing) can also be demonstrated experimentally by the animal experiments of Ehrlich and Hata.

Compounds containing arsenic of three valences are good therapeutic agents as they are: 1, basic substances and therefore react powerfully with the acid cell constituents, and 2, more powerful oxygen abstracting agents than the compounds with five valences, which lack this property. In addition to these differences the most important factor of all has to be considered, namely: the difference in the lipoid solubility, for which reason arsenicals with trivalences can be bound by the living cell, while arsenicals with pentavalences cannot. This will again be referred to later. Up to this point the results of my investigations have already been discussed in Munich. While we had already formed a certain general idea of the mode of action of salvarsan numerous points still lacked a satisfactory explanation. It was evident that salvarsan owed its effect neither exclusively to its arsenic content nor exclusively to its reduxophore groups. If this were the case, there would be no reason why sulphurated salvarsan, which also carries the arseno and the same reduxophore groups, should develop a dystherapeutic action similar to the isomere of salvarsan, the 2, 2′— dioxy —4, 4′— diamidarsenobenzol. It was evident that some other till then unknown factor was playing an important part. This factor lies in the chemical structure of the spirochete. Strictly speaking, we know nothing about this structure except that the spirochete is poorer in oxygen than the body cell. Research work arrived at this deadlock several years ago and has remained there. Nor was progress possible as we did not know that class of substances which forms the main structural elements of the spirochete, namely the lipoproteids (lipoid albumin compounds). Progress beyond this stage was possible only after we had succeeded in explaining the gram stain. The latter we know now is due to the content of gram positive lipoproteids in gram positive microorganisms, as was shown in my paper read at Goettingen this year (7).

This paper also shows how my own investigations would have arrived at a deadlock had we not penetrated more deeply into microchemical processes. Those who worked in this direction were reminded of an observation which was made years ago, namely, the identical response of body and spirochete cells to the Giemsa stain on the one hand, and of nucleic acid yeast cells and yeast cells artificially freed of nucleic acid, on the other.

Everything pointed to a lipoid content of the Spirocheta pallida and it was shown in a previous publication (8) that the pallida is actually built up of a gram negative lipoproteid. At this time it was also observed that if the nucleic acid is withdrawn from yeast cells and their lipoproteids remain, the stains of the fuchsin group, in particular victoria blue, prove to be a lipoid stain par excellence. The Spirocheta pallida can therefore be demonstrated particularly well with victoria blue, as Muehlpfordt also discovered, empirically, independently of my investigations. From this knowledge of the lipoproteid nature of the Spirocheta pallida it was evident that the staining of the latter could be considerably improved upon by staining not only one of the constituents of the spirocheta lipoproteids (the lipoid acid) with the basic victoria blue, but also the other component of the lipoproteid, the basic albumin, with an acid blue stain, by which a summation of the staining effect results, especially if alkali blue, a slightly lipoid-soluble blue stain is chosen. These conclusions led to my development of a very bright stain for spirochetes, which I have already described (9). It was furthermore necessary, in order to complete our knowledge of the action of salvarsan, to investigate the chemical composition of the salvarsan alteration products after oxidation has taken place. As has been mentioned, air was led for a certain length of time through an alkaline solution of old salvarsan for this purpose, and the precipitate examined. By its reactions this proved to consist of the free salvarsan base. The solubility in alkalies, the insolubility in water and the reactions to a lecithin ether solution, to alcohol, benzol and ether already pointed to this. Independently of my investigations, Kritschewsky has recently demonstrated, as I learn from the new manual of Kolle and Zieler, that the sediment which forms in salvarsan solutions consists of the salvarsan base which is split off by hydrolysis. Furthermore, if we consider that the living yeast cell binds the maximum of salvarsan *at the very moment* the salvarsan solution begins to release the base, the connections are explained.

It was evident that some relation must exist between the lipoproteid content of yeast and the developing water insolubility of the salvarsan base. It was probable also that an increased lipoproteid solubility of the salvarsan base would develop. (This actually occurs.) These conclusions led me to search for the underlying causal connections. If the above assumption is correct it follows that living yeast cells must chemically bind a freshly prepared salvarsan base (prepared by precipitating with NaOH from old salvarsan and then rinsing). This is actually the case, as can be demonstrated by shaking up living yeast cells with a freshly precipitated and rinsed salvarsan base. This is allowed to stand for a few hours, then rinsed again and treated with an ammoniated silver nitrate solution.

Only one question remained unsolved now:

Does, in the event of such a selective storage of the salvarsan base by the lipoproteids of yeast, a formation of salt take place, or is the salvarsan base

only bound by absorption? This question could, of course, not be answered directly with regard to salvarsan. However, the above finding led me to investigate the action of the violet black victoria blue base (which is practically water insoluble though more markedly lipoproteid soluble) on living yeast cells, anthrax bacilli and spirochetes as I have explained in my paper, A Note on the Demonstration of Bacterial Nuclei and the Chemistry of Disinfection read before the Berlin Microbiological Society, November, 1924. If the victoria blue base is applied to these microorganisms they store the base *selectively* and stain *blue* in the color of the victoria blue salts and not red, provided a simple solution of the victoria blue base took place. I might add that the above microorganisms respond in the same way to the absolutely colorless new fuchsin base. They stain red with the color of the salts of this base, which proves that the disinfection of the cells in these cases, chemically represents a salt formation. One could also demonstrate this by not applying the dye bases but their salts and by finding chloride in the centrifugated fluid. This would also point to a salt formation, provided the yeast cells treated with a fuchsin solution contain only lipoproteids and have previously been freed of their nucleic acid content. It follows, therefore, that the selective storage of the salvarsan base by the lipoproteids of yeast cells must take place in the sense of a salt formation, as salvarsan would otherwise be eliminable through rinsing as is the case when living yeast cells are treated in the same way with intact salvarsan.

I therefore conclude that if the microchemical findings are correct and if the Spirocheta pallida and the other spirochetes are built up of a lipoproteid they must be able to bind both the salvarsan base and the victoria blue base selectively and would consequently have to stain *blue* with the victoria blue base. This is actually the case. Both the buccal spirochetes and the recurrens spirochetes (in the blood of mice afflicted with recurrent fever) stain blue in the hanging drop after some time with the victoria blue base. This can also be shown with the pallida, though not as easily because of its more delicate structure. These experiments, however, do not enable us to demonstrate the binding of salvarsan to spirochetes, as sufficient quantities of parasites for exposure to the action of salvarsan are not available and one cannot rinse them and then treat them with a silver nitrate solution. However, one can demonstrate this *in vivo* which is still more convincing. In this way we can, as it were, confirm our micro*chemical and analytical findings macrochemically.*

To return to our experiments with the alteration products of salvarsan and living yeast *in vitro.*

Living yeast cells bind little unaltered salvarsan. If the contrary were the case, a quantity of yeast which has been treated with an unaltered alkaline solution of one one thousandth old salvarsan, when centrifugated, rinsed and freed of its salvarsan would have to turn brown black following an aftertreatment with an ammoniated silver nitrate solution. This is not the case. Macroscopically the yeast only appears light brown. Microscopically one recognizes all living yeast cells as absolutely colorless while dead specimens are stained deep brown.

A method for distinguishing living and dead germs is based on this observation (10). The further salvarsan is oxidized through passage of an air current, the darker (black) the corresponding yeast tubes will appear if treated later with an ammoniated silver nitrate solution. The moment a deposit forms in the salvarsan solution the cells stain deep black, that is, they have bound the maximum quantity of salvarsan. Vice versa, one can prove that the cells have bound a maximum of salvarsan at this moment, as the salvarsan solution when removed (by centrifuge) after the yeast cells have exerted their action, *does not stain so intensely brown.* In fact, the intensity of the staining decreases with the duration of the action of the yeast cells on the salvarsan solution. One can also prove that the deposit which is formed consists of the salvarsan base, as the reaction to water, alcohol, ether, benzol and lecithin ether readily shows. If neosalvarsan in a concentration of 1:1000 is chosen for the same experiment only very little of it is bound to the cells after oxidation, in contradistinction to old salvarsan. To bind the same quantity of neosalvarsan as of old salvarsan to the cell, ten times the concentration of the former is required. Silver salvarsan acts in the same way as old salvarsan.

These tests show that if salvarsan is oxidized, the formation of p-oxy-m-aminophenylarsinoxide does not occur immediately, as has generally been assumed. The salvarsan base is precipitated first, the oxide mentioned being formed later, as one can judge by the dirty brownish discoloration of the solutions. The fact that this progressive oxidation occurs comparatively slowly is also proved by the prolonged preservation of the dirty yellowish sediment during the subsequent oxidation process. This sediment would have to disappear more quickly if the change into the p-oxy-m-aminophenylarsinoxide took place quickly, the latter being readily soluble in water.

What happens *in vivo?* The following are the possible alteration products of salvarsan:

One can rule out the p-oxy-m-aminophenylarsinacid as the possible effective alteration product of salvarsan *in vivo* for the following reasons: it is rendered practically lipoid insoluble, through arsanilization, as can be shown by letting its aqueous solution or a solution of its sodium salt act on lecithin ether and then subjecting it to an ammoniated silver nitrate solution. We have, furthermore, demonstrated that spirochetes are only able to bind selectively lipoproteid soluble[2] more markedly than water soluble substances. Such a binding would therefore be impossible owing to the physical properties of the arsin acid. The inefficiency of the latter against parasites *in vitro* has also long been known. If salvarsan, therefore, acted *in vivo* only after its change into the arsin acid, it could not produce clinical results for the reasons given.

(*To be concluded*)

[2]Lipoproteid solubility and lipoid solubility are not identical. The victoria blue base, for example, is bound selectively by lipoproteids and forms the corresponding dye salts with these, while cholesterin, on the other hand, cannot bind the victoria blue base selectively nor does it form a dye salt. This is proved by the fact that cholesterin-ether dissolves the dye base in the same quantity with a red color as does ordinary ether. Nor is a salt formation probable as cholesterin is an alcohol. This is also the reason why red blood corpuscles do not stain blue when fresh blood is mixed with the victoria blue base, while the lipoproteids alone turn blue. This experiment therefore enables the staining only of the parasites and of the lipoid containing protoplasm of the white blood corpuscles and not of the nuclei.

Practical Therapeutics

MERCURY IN THE TREATMENT OF SYPHILIS

L. Spiegel, M.D.
New York

According to Stokes (1), mercury was perhaps first employed in the treatment of syphilis during the latter part of the fourteenth century and early in the fifteenth century. Garrison (2) states that in the twelfth century, mercury salve was applied as a treatment for various skin diseases, and special mention is made of the efficacious action of mercury salve in the relief of certain classes of skin lesions. This might suggest that the certain kind of skin lesions referred to, that is the ones yielding so well to the influence of the mercury salve, were really luetic manifestations. Even the Arab physician, Astruc, knew of the value of mercury ointment and accordingly made use of it in the treatment of certain skin conditions. It is significant that since as early as the twelfth century mercury in some form has been used in medicine.

In this paper we are only concerned with its therapeutic application in syphilis. If we accept either the theory that syphilis first appeared in Europe following the return of the Columbian expedition from Haiti in 1493, or the notion that it became pandemic during the early part of the fifteenth century and that it existed perhaps centuries before, appearing here and there endemically, then we must accept the fact that even in those early times mercury was the chief therapeutic agent for the treatment of those skin diseases, which would probably be called syphilis today.

Mercury was first applied as a salve or ointment (inunction cure), then orally, either alone, in the form of a salt of mercury, or in combination with other chemicals (mixed treatment), and according to Shoemaker (3), in 1865 its first administration in the form of the sublimate salt by hypodermic injection was made by George Lewin at the Royal Charity Hospital in Berlin. With mercury, as with other drugs, harmful effects have been reported from time to time, and some salts or compounds of mercury have fallen entirely into disrepute because of untoward reactions following their use. Following the discovery of salvarsan by Ehrlich (4) in 1910, there existed for a time a tendency to discard mercury in favor of this newly discovered drug, but it was soon shown that salvarsan alone could not accomplish everything, and that the use of mercury, the old standby, in conjunction with salvarsan gave better results. Mercury and salvarsan together, it has been shown, accomplish more in syphilis than either of the two alone, and rarely does a syphilographer today depend entirely on only one of the two drugs.

Of late another drug, bismuth, in various forms, either the soluble salts or the insoluble salts, has come into use as an antiluetic remedy, but as yet, not a great deal can be said concerning the value of the drug. Kolle (5), working with rabbit syphilis, has shown that the soluble salts are not very effective spirocheticides but that the insoluble salts produce some beneficial action. He did not find that it equaled either salvarsan or mercury in effectiveness. It is, perhaps, more useful if the spirochete has become fast to either the action of salvarsan or mercury, or when a patient is hypersensitive to the effects of one or the other of these two drugs. In the opinion of the writer it ranks third in the antiluetic drug armamentarium. Ballenger and Elder (6) assert they have obtained excellent results with a suspension of bismuth salicylate in oil. According to them it was most valuable in cases where the spirochete was "fast" either to salvarsan or mercury. They used it together with salvarsan and mercury and reported good results in a number of cases. It remains to be seen, however, if the three in conjunction, namely, salvarsan, mercury and bismuth, will accomplish any more than the two former alone.

In my opinion, salvarsan and mercury are absolutely essential. The selection of the safest and most dependable forms of these two drugs is of great importance, as is the mode of their administration. After careful observation for almost two years, I have concluded that the best results follow the administration of silver-salvarsan, as the arsenical part of the treatment, and mercurosal, an organic compound of mercury, as the mercury end of the treatment. The two have been administered intravenously to a number of patients.

According to Rowe (7) mercurosal, a water soluble compound of mercury, conforms to the following chemical formula: Disodiumhydroxymercurisalicylacetate. The drug contains about forty-four per cent. of the metal and is relatively less toxic, in spite of its higher mercury content, than the salts of mercury more commonly employed. The following table will serve as a comparison with other sales of mercury:

	Average Dose		*Mercury Per Cent*	*Amount of Mercury Per Dose in Grains*
	Metric	*Grains*		
Mercurosal.....	0.1	1½	44% approx.	.66
Mercury oxycyanide..	.008	⅛	82.5	.103
Mercury bichloride...	.032	½	74.	.37
Mercury salicylate....	.065	1	59.5	.595
Mercury succinimide.	.010	⅙	50.5	.084
Mercury iodide.....	.010	⅙	44.	.073
Mercury protoiodide..	.010	⅙	61.1	.102
Mercury benzoate....	.008	⅛	45.25	.0566
Mercury cyanide.....	.010	⅙	79.4	.132

It is obvious from this table that, based on actual mercury content, more mercury per dose can be safely delivered into the blood stream with mercurosal than with any of the other salts. It will also be seen that mercurosal has a higher mercury content per average dose than even the insoluble salts of mercury which, of course, cannot be given intravenously. In the article by Rowe referred to above, after careful animal experiments with various salts of mercury and mercurosal, he concludes that mercurosal is only one fifth as toxic, even when equivalent mercury content is considered, as such salts as the bichloride, iodide, salicylate or succinimide.

Opinions differ as to the relative values of soluble and insoluble salts of mercury. The suggestion is

sometimes offered that insoluble salts, because of their slow absorption from the tissues, are more valuable because a constant mercury effect upon the spirochete is thus produced, whereas, with soluble salts the mercury effect is only for such time as the mercury remains in the blood circulation. The clinical results obtained by the writer using mercurosal, a soluble salt of mercury, did not confirm such suggestions—the contrary was apparently true. A full mercury effect was produced with mercurosal and this could be maintained by successive doses of the drug given at regular intervals. With insoluble salts care must be exercised because of the cumulative action, due to the fact that the rate of absorption from the tissues cannot be controlled. With mercurosal a definite dose can be given and the dose repeated without fear of cumulative action because the drug is eliminated at a definite rate. The occurrence of a condition such as a fastness of the spirochete to mercury may be due to the fact that the full mercury effect is never fully obtained from insoluble salts of mercury, the action of mercury in this form not being sufficiently spirocheticidal. With an adequate dose of mercurosal a spirocheticidal effect is produced, as evidenced both by a rapid disappearance of the lesions and a reduction in the blood Wassermann. In my clinical work, doses of two decigrams of mercurosal, two ampoules at a time, have been administered without producing untoward reactions. When slight mercurialism did occur, the symptoms were readily controlled, either by suspending treatment for a time or by applying the usual remedial measures. As much as two tenths or two ampoules three times a week, a total of six tenths of mercurosal, have been administered to get a full mercury effect rapidly and no untoward reactions occurred. I do not think it advisable to give so much of the drug to begin with, unless the patient's tolerance has been previously determined. In the cases treated with these large doses, smaller doses, gradually increased, have indicated the patient's tolerance. It might be well to point out that it is extremely important to make sure that the patient's power to eliminate properly the drug is not hampered by a kidney condition or other cause. In an article by Gruhzit (8) it has been shown, as a result of careful animal experimental work, that mercurosal in doses of three tenths in a week is spirocheticidal and this dose may be continued for a long time without injury to the patient. The work of Gruhzit has been confirmed clinically by Belding and Holmes (9) in their report of the effects of mercurosal upon the Wassermann reactions of patients treated by them. The writer's results are quite in agreement with the findings of Belding and Holmes and in accord with these two investigators that intensive treatment should be the rule and not the exception. In my clinical work, both silver salvarsan and mercurosal were used in the treatment of the cases. No untoward or harmful effects resulted from their use, either in separate courses or by alternating the two; for example, one day silver salvarsan, the next day mercurosal. Improvement of the lesions was invariably prompt, and in most cases the blood Wassermann was decreased after a few courses or soon became negative. Of course, the writer does not wish to give the impression that every case treated became negative or that mercurosal and silver salvarsan reduced all of the socalled Wassermann fast cases. However, the point that will interest the clinician is the fact that both silver salvarsan and mercurosal are dependable and potent drugs.

In the treatment of the series of cases upon which this article is based, comprising primary, secondary and tertiary cases of syphilis, the technique has been as follows: After the diagnosis had been made, the patient's urine was carefully examined. This was done in order to determine if a kidney condition existed that might contraindicate the use of either salvarsan or mercurosal. If the urine analysis revealed no evidence of serious kidney pathology, the treatment was begun.

TECHNIC

In cases of primary or secondary syphilis four doses of silver-salvarsan, three tenths on successive days (Pollitzer (10)) were administered intravenously. After an interval of two days, eight or ten doses of mercurosal one tenth were administered, one ampoule either every third or fifth day (using the same vein through which the silver-salvarsan was given). If the patient happened to be a child or an undersized adult, the dose was made proportionately less. Usually half an ampoule of mercurosal was well borne. If the patient's tolerance was good, the next dose given was a full ampoule or one decigram. After two days more, silver-salvarsan three tenths was again given but now only twice a week until six doses had been administered. This was followed again by mercurosal one tenth, one ampoule, every five days until eight doses had been administered. This usually constituted the first course of treatment. The patient was then permitted to a rest period of four weeks in the early cases. After the rest period, before beginning the second course of treatment, a blood Wassermann was made. The second course of treatment consisted of weekly doses of silver-salvarsan three tenths, and between the weekly doses of the silver salvarsan, one ampoule or one tenth of mercurosal, usually eight to ten doses of each. After this course the regular rest period of a month to six weeks was again allowed the patient, and before beginning a new course of treatment, a blood Wassermann was again made. The treatment as above outlined, namely six to eight doses of silver-salvarsan three tenths and mercurosal one tenth (one ampoule), one of each was again repeated as outlined above, and this intensive treatment continued for the first year regardless of the Wassermann being negative or not. After the Wassermanns had remained negative, an examination of the spinal fluid was recommended. If the findings proved negative, the patient was discharged with of course the warning, to return from time to time for a blood examination. In fact, the patient was advised to have a Wassermann made about every four or six months for the next two or three years.

In the tertiary cases the same procedure was followed with regard to the routine uranalysis before beginning treatment. The treatment consisted of a course of silver salvarsan three tenths once a week for from six to eight doses, and mercurosal one tenth (one ampoule) once a week between the doses of silver-salvarsan, until ten or twelve doses had been

administered. The regular rest periods of six weeks were allowed following the courses of treatment and the Wassermanns were made at regular intervals before beginning a new course of treatment.

For a year the urines of all patients treated were carefully watched, and not in one instance did the treatment produce or give rise to any kidney symptoms. Frequently all of the medication was delivered through the same vein and no injury to the vessel resulted. Patients who had received medication intramuscularly with insoluble salts of mercury before, very often, after receiving intravenous injections of silver-salvarsan and mercurosal, flatly refused to be treated any other way thereafter. It was easier to get patients to return regularly for treatment when the medication was administered intravenously because they never suffered from any pain or swelling, the discomfiture frequently caused when intramuscular medication is used.

I wish to emphasize the fact that mercurosal, in my clinical experience with it, did not produce injury to the veins.

I have selected a few cases from quite a large series treated in the manner outlined above. The case histories and treatment were as follows:

Case I.—A. L., male, U. S., aged forty-five. Chancre present eight or nine days. Darkfield examination from lesion. Spirochete present. Wassermann examination December 16, 1924, two antigens, four plus. Treatment: silver-salvarsan three tenths administered intravenously on the following dates: December 22nd, 23rd, 24th, 26th, 29th, January 2, 1925. Mercurosal, one ampoule, one tenth intravenously administerd on the following dates: January 5th, 9th, 14th, 19th, 24th, 29th, February 3rd, 8th, 15th, 20th. One month rest period allowed patient. Wassermann February 22, 1925, two antigens, both negative. Treatment resumed—silver-salvarsan three tenths administered on the following dates: March 23rd, 27th, 30th, April 3rd. Mercurosal, one ampoule one tenth, ten doses during period from April 10th to May 10th. Rest period then allowed patient—six weeks. Wassermann June 24th, two antigens, both negative. Patient now receiving another course of treatment.

Case II.—S. A., female, aged nineteen. Chancre of tonsil, mucous patches, adenopathy. Wassermann November 11th, four plus. Treatment: silver-salvarsan November 16th, 18th, 20th, 23rd, 25th. Mercury salicylate, four intramuscular injections. Patient refused to have salicylate of mercury injections on account of pain. Treatment resumed—silver-salvarsan three tenths intravenously January 11th, 14th, 18th, 21st, followed by mercurosal, one ampoule one tenth intravenously January 24th, 29th, February 5th, 9th, 13th, 19th, 24th. Wassermann February 26th, two antigens, negative. Treatment continued. Silver-salvarsan March 7th, 14th, 21st, 28th. Mercurosal weekly April 1st, 8th, 15th, 22nd, 29th, May 13th. Wassermann May 27th, two antigens, negative. Silver-salvarsan June 13th, 20th, 27th, July 11th. Mercurosal August 12th, 19th, 27th, September 3rd, 10th, 17th. Silver-salvarsan January 12th, 19th, 26th, February 9th. Then mercurosal weekly, ten doses from February 2nd to April 21st. Wassermann, two antigens, July 1st, negative.

Case III.—R. A., female, aged thirty. Infected 1920—tertiary syphilis. Symptoms—small gummata of face and arms. Patient had received previous treatment of fourteen salvarsan and twelve mercury salicylate injections before coming under my care. Last Wassermann reported to be two plus. Wassermann May 22, 1923, two antigens, both four plus. Treatment: silver-salvarsan, three tenths May 28th, June 1st, 4th, 8th, 11th, 15th. Mercurosal, one ampoule one tenth, at five day intervals, until eight doses were administered, from June 19th to July 24th. Rest period allowed until October 1st. Wassermann then two antigens, both two plus. Treatment resumed—silver-salvarsan and mercurosal intravenously, given alternately—October 6th, 9th, 13th, 17th, 21st, 24th, 28th, November 1st, 4th, 7th, 11th. Mercurosal was now given alone on the following dates: November 14th, 19th, 24th, 29th, December 4th, 9th, 15th, 20th. Rest period to January 15, 1925. Wassermann then, two antigens, both negative. Treatment resumed—silver-salvarsan and mercurosal administered alternately during February and March—February 9th, 13th, 16th, 20th, 23rd, 27th, March 2nd, 6th. Then mercurosal as follows: March 13th, 20th, 27th, April 3rd. Rest period to July 14, 1925. Wassermann made, two antigens, both negative.

SUMMARY

1. It would appear from the literature that mercury was as old in the treatment of syphilis as the modern recognition of the disease itself.

2. That salvarsan and mercury together give the best results, especially when these drugs are administered intravenously.

3. That bismuth is of distinct value in the treatment of syphilis but that it has not the spirocheticidal action of either mercury or salvarsan and therefore further observation and study of its action will be necessary before any definite conclusions can be drawn.

4. That silver-salvarsan and mercurosal give excellent results when both are administered intravenously and when intensive treatment with both is made the rule.

5. That mercurosal has a higher mercury content than the usual salts of mercury employed, and that its toxicity is lower.

6. If proper attention to the patient's elimination is given and the patient's tolerance to the drug is carefully observed, as high as two tenths (two ampoules) of mercurosal at one time may be given without danger to the patient.

7. That mercurosal does not usually produce a severe mercurialism or stomatitis when given ever over a long period of time, and that when such symptoms do appear, they are amenable to simple treatment.

8. That patients, having once received mercurosal by the vein route, invariably rebel against the use of the insoluble salts of mercury by intramuscular injection.

9. That no injury to the vein results from the use of mercurosal and that no kidney injury is produced from its use alone or in conjunction with silver salvarsan.

The Physician and the Patient of the Future

Presidential Address

WENDELL C. PHILLIPS, M.D.

New York

Who can visualize or define the physician and the patient of the future? Human progress has always been associated with epoch making discoveries, and medicine, with other sciences, has blazed an enviable trail along the pathway of the ages. The marvelous achievements of the men of medicine of today are largely the outgrowth and fruition of similar achievements of the founders of our art. The history of no other science contains brighter pages than those illumined by the scientific conquests of the great men of medicine. The new developments in medical science have created the necessity for changes in modes, methods and economies so far reaching as to affect all phases of national, family and individual life. The physician both of the present and of the future must be an integral part of our civilization and much concerned with its changes.

THE HERITAGE OF THE FUTURE PHYSICIAN

Human sympathy evolved a desire in men to relieve sickness and sorrow. Sixty centuries have elapsed since Egyptian medicine first made its imprint on humanity. The Greeks gave us a new conception of medicine as an art. True, the early leaders in medicine were not only physicians but also priests and philosophers with little knowledge of anatomy, physiology or chemistry; but they implanted into the basic structures of our science the spirit of the healer.

Born four hundred years before Christ, surrounded by all that Greek culture and education meant in that day, Hippocrates was justly acclaimed the ideal physician, the great teacher and the founder of modern medicine. He not only taught his pupils what he knew of medicine, but he ever insisted that they should enter into professional life with high ethical ideals, which time has never effaced. To him we owe the formulation of the renowned hippocratic oath. By that vow the physician pledged himself to his teachers, and to disseminate to those who followed him the knowledge that he acquired. He pledged himself to follow that system of treatment which, according to his ability and judgment, would be for the benefit of his patients, and to abstain from whatever was deleterious and mischievous. He foreswore all harmful methods and resolved himself to practise for the benefit of the sick. "Whatever, in connection with my professional practice, or not in connection with it, I see or hear, in the life of men, which ought not to be spoken of abroad," he said, "I will not divulge, as reckoning that all such should be kept secret."

In those earlier periods, nothing was known of pathology and there was no scientific basis on which might be based a reasonable understanding of the causes of disease; nor had the physician or the patient the benefits to be derived from hospital or laboratory. But as time went on diphtheria, plague, tuberculosis, gynecological diseases, obstetrics and affections of the eye, ear, nose and throat and many other diseases were fairly well defined.

The thirteenth century marked the foundation and rise of the universities and the gradual development of methodical medical studies. Dissection became more common; hence, the knowledge of anatomy and surgery progressed. Conscientious surgeons undertook serious operations without fear of criticism.

At this period few of the world's inhabitants reached adult life without an attack of smallpox. About 1796, Edward Jenner, practitioner of Gloucestershire, in England, boldly transferred cowpox infection from the hand of a young milkmaid into the arm of a young lad named Phipps, and immediately established the fact that immunity could be produced As the result of vaccination, smallpox, the dread blemisher of human beauty and destroyer of human life, has become a thing of the past, except with people who foolishly neglect to avail themselves of the protection thus provided. But for Jenner's discovery, the faces of at least fifty per cent. of this audience would be marred by pockmarks. The decimation of cities and communities from smallpox had continued throughout the centuries. But for this discovery, the continued high death rate from smallpox in foreign countries would have made it impossible for the United States in 1926 to have anything

like a population of one hundred and ten million. In the light of this great discovery and boon to humanity, the proofs of which are positive and unassailable, is it not strange that prejudiced, benighted individuals and believers in cults like the antivivisectionists, the antivaccinationists, the chiropractors and the Christian Scientists, should presume to question the effectiveness of vaccination and unhumanly attempt by precept, by example and by propaganda to prevent its employment? Unfortunately, during the last few years in various parts of our country these forces for evil have succeeded in creating prejudice. Neglect of protective vaccination against smallpox has resulted in more or less alarming outbreaks of the disease. The state of Florida has just furnished an example of this kind. Wherever states have been lax regarding the vaccination of school children, smallpox has spread, and yet this disease is an example of contagious disease which we know positively can be prevented.

Louis Pasteur, father of the conception that bacteria (germs) are the direct cause of many diseases, gave to the world the key to the causes of putrid and suppurative diseases. Then came a positive demonstration of a specific germ—Robert Koch's discovery of the bacillus of tuberculosis.

Surgery adopted the principles first of antisepsis and later of asepsis. Few surgeons had ventured previously to perform major operations on the vital portions of the body, on account of the frightful mortality which resulted from suppuration. Joseph Lister, in 1878, showed how bacterial infection of wounds may be prevented by applying the principles of antisepsis in surgical operations. This momentous discovery revolutionized surgery and greatly lowered the mortality from surgical operations. Today surgeons, applying aseptic principles, do not hesitate to operate on any portion of the body, even the human heart.

In the fifty years since the discoveries that have just been mentioned, chemistry in medicine has made rapid strides, particularly in its relations to studies in physiology and metabolism. Chemical estimation of blood urea, proteins and gastrointestinal contents and laboratory studies in cardiorenal and blood efficiency enable the physician to estimate the conditions of important organs of the body.

Meanwhile, physics, pathology, bacteriology, sanitation and preventive medicine have been developed to a high degree. The discovery of antitoxin for diphtheria has proved a boon to the child. The various animal carriers of disease have been determined and classified.

The work of Gorgas in making possible the building of the Panama Canal by the application of our knowledge of insect transmission of yellow fever and malaria, and the employment of antityphoid and paratyphoid vaccine, together with sanitation of water and food supplies, have practically annihilated these diseases. The future may bring about the complete eradication of diphtheria, scarlet fever, whooping cough, and possibly all the exanthems; while yellow fever, typhus fever and all plagues are falling before the gigantic march of preventive medicine, based on bacteriological discoveries.

This has been the contribution of the physician to the march of human progress. Truly, neither the physician of the present nor the physician of the future need ever blush when contemplating his professional heritage.

CHANGES IN PRESENTDAY MEDICAL PRACTICE

We build on the experience of the past. The rapid strides in medical discoveries of the last two generations, together with the more practical employment of sanitation and preventive medicine, have already effected great changes in the actual duties of the practising physician. The daily round of our immediate predecessors was made up largely of the treatment of infectious and contagious diseases. The daybook of the family physician usually recorded visits to families for the treatment of measles, scarlet fever, diphtheria, typhoid fever or malaria only. He was educated to treat disease. He knew little of preventive medicine, sanitation or hygiene, nor did his medical education provide such knowledge. Older living practitioners know of the changes which mark the new era only by keeping abreast of the times.

National, state and municipal departments of health have gradually become powerful and controlling factors in preventive medicine, sanitation and hygiene. Health and welfare organizations, both national and local, have also invaded the field of preventive medicine. Great industrial organizations have introduced various health measures, believing it to be for their own best interests from an economical viewpoint, as well as for the benefit of the hundreds of thousands of employees. Pay clinics and group practice have made some slight imprint on the modes of practice of today. Furthermore, the publicity work of all these agencies, together with that of our own association, has gradually created a demand from the public for more information regarding personal health. The outcome of these measures has led to confusion regarding not only the present but also the future of medical practice. But the confusion of the present need never become chaos in the future, provided the medical profession prepares to meet the demands of the patients of the future.

HEALTH EDUCATION FROM THE VIEWPOINT OF THE PUBLIC

The new era in medicine which the physician of the future must be prepared to enter must also rest on the foundation of a wide and comprehensive plan of personal and public health education. Professional policies, narrowly conceived, can never successfully oppose the rightful interest in the public. The failure properly to educate the public regarding the achievements of medicine and its importance in the preservation of life and the prevention of sickness may be considered as such a policy.

The editors of great daily newspapers and magazines, the newspaper syndicates, and university and public school teachers are calling on the medical profession as never before to enter this field. They properly contend that the educated physician must remain the source of personal and public health education. The *Saturday Evening Post* recently said that the "science of medicine, as far as laymen are concerned, is the most tonguetied of all the learned professions." It called attention to the difficulties surrounding the scientific vocabulary of medicine as a means of teaching the public, and the shrinking atti-

Piracy Still Exists

One doctor describes the modern pirates as "nefarious blackmailers, the ever grasping base character assassins and what not that infest and permeate more or less every community and not the least, the shyster lawyer."

Read what one of your colleagues says regarding Medical Protective Service in combating such piracy:

> "As I review the case from beginning to end I am filled with admiration at the expert handling of this case. It certainly gives the professional man a feeling of great security to know he has the protection of a legal company against these hold-up people, who prey upon the professional man at each and every opportunity, where they think there is a possibility of getting some easy money. However, this type of individual is what we are up against, and it is a godsend that we have the Medical Protective Company who know how to handle these fakers."

A malpractice charge is no respecter of persons; the time of the attack cannot be foretold; past immunity is no guarantee to future safety.

For Medical Protective Service have a Medical Protective Contract

THE

tude of the medical profession toward the lay press. Then followed the statement:

"The enlightened physician has a great body of news of the highest importance to communicate to nonmedical readers. When the medical profession becomes more fully awake to its responsibilities in this field, it is to be hoped that it will perceive the gravity and importance of its problem and attack it in force over a nationwide front. Some national body, such as the American Medical Association, which has made such a good start along these lines, ought to take up the matter in a big way and work out a comprehensive program which would unify the efforts of the agencies already in the field, and cover the lay press of the whole country."

These friendly criticisms are perhaps well deserved. Our answer is that organized medicine has already entered this field. Considerable progress has been made in overcoming the reticence of medical men when called on to prepare health talks for audiences or the radio, or to write articles for lay publication. The prejudice that has existed against these measures is being dispelled. If the radio had been available during the ministry of the Great Physician, he would have made it hum and thrill while it adroitly advertised his message. The radio likewise should serve the physician and be made by him to illuminate his gospel of good health. Medical men now prepare articles for magazines, for the radio and for the public press covering all the phases of medical knowledge.

I am proud to state with the greatest emphasis that the medical profession is well able to supply the brains for any and all nation wide efforts for individual and community health education that the great business publications and the advertising world will undertake to promulgate and finance. This statement is the challenge of organized medicine! I pledge its fulfilment so far as lies within my power, and I sincerely hope that influential laymen of our country will accept the challenge.

Physicians until recently have contributed insufficiently to public health education. Today every licensed physician is being urged to prepare himself to teach his own patients the principles of health. Sufficient progress has already been made to warrant the statement that the field of public health education must and should be invaded by the physician. Organized medicine has approved this measure. The House of Delegates of the American Medical Association is on record as favoring every measure of public health education, including periodical medical examinations of the supposedly healthy. Two years ago the board of trustees entered this field on a larger scale by establishing *Hygeia,* a monthly public health journal published distinctly for the lay public. *Hygeia,* devoted to individual and community health, has already qualified as the leading public health journal of America. Its columns contain information of the utmost value covering the whole field of medicine. The lay reader is told what to do and what not to do regarding health affairs, and every issue contains exposures of vicious nostrums and quackery. Clip sheets from every issue of *Hygeia* are furnished to hundreds of newspapers, so that already millions of our people are receiving this direct and valuable health service.

Furthermore, many of our great newspaper syndicates, great daily newspapers and reputable magazines refuse to publish any material pertaining to health except on reliable medical approval. The propaganda of quackery and vicious nostrum advertising are refused by these great publications in the interest of the public health. Indeed, in health matters, many of these publications rely constantly on the advice received from the American Medical Association headquarters. Radio instruction in public health is rapidly increasing as a result of definite programs arranged by state and county medical societies. Other legitimate public health agencies are also active in this field.

PERIODICAL PHYSICAL EXAMINATION

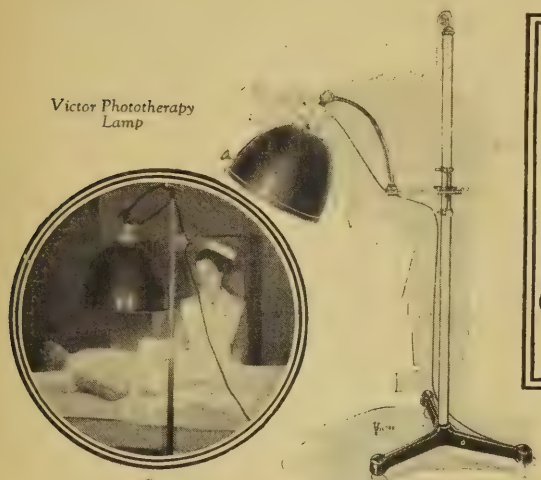
Periodical physical examination of the supposedly healthy is a public health measure that has the approval of the medical profession. The members of state and county medical societies are being urged not only to undertake the actual work of examination but to promote this healthful measure. The task of educating the one hundred and twenty million people of our country in personal and public health matters is stupendous, and its promulgation will require the combined efforts of medical men as teachers, of influential laymen and great publications as promoters. Physicians believe that whenever this great task shall have been accomplished in any nation, state or community, the average life of the inhabitants involved will be increased at least another seven years over the twenty that have been gained in the last half century.

Knowledge of the great principles involved in the preservation of health and of the great historical proof of preventive medicine will lead legislators and others in responsibility to protect every community against the blandishments of unlicensed quackery, the enmity of antimedical propagandists, and the evils of nostrum medication.

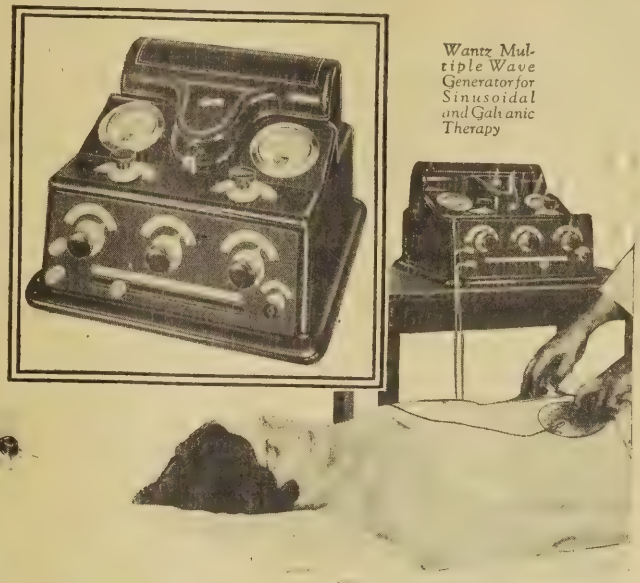
Public officials are already beginning to appreciate their responsibility regarding public health measures. In his recent message to the New York State legislature, Hon. Alfred E. Smith, governor of New York, proclaimed that "one of the great functions of government is the preservation of public health." He further said:

"I renew the recommendation of a year ago that careful consideration be given to the protection of the people of the state from unlicensed and unqualified persons practising medicine. The cooperation of the medical profession is an essential factor in the protection of the public health, as well as in the care of the sick. A very large part of modern public health is urging people to get the advice of their physicians before serious and perhaps incurable conditions have developed. Such effort comes to naught if unqualified persons are allowed to hold themselves out as physicians. The subject is a difficult one, but the state of New York should take the lead in establishing high standards of medical practice, and providing a practicable plan for their enforcement. It is a matter of justice to qualified physicians and of protection to the public."

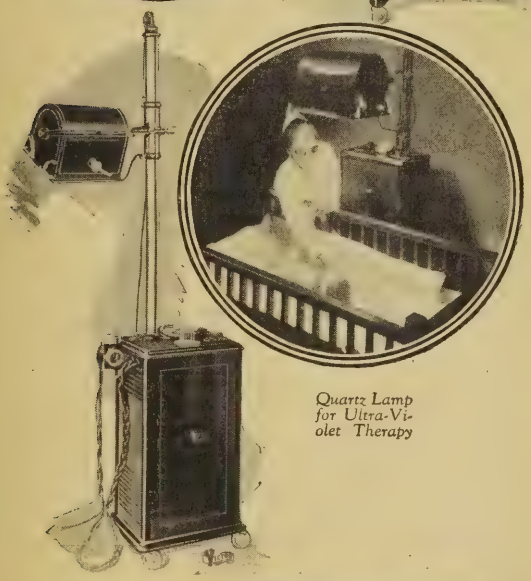
Let us hope that all state governors and all legislators will emulate the fine example of humanitarianism set by the governor of the Empire State.



Victor Phototherapy Lamp



Wantz Multiple Wave Generator for Sinusoidal and Galvanic Therapy



Quartz Lamp for Ultra-Violet Therapy

Two-Section Mobile Diathermy Apparatus

The Physical Therapeutist Must Approve

It is the physician who dictates the design and construction of Victor apparatus for physical therapeutics.

Before a diathermal or a sinusoidal-current machine, an ultra-violet or phototherapy lamp is designed the requirements of medical practice are determined. Victor research then conducts an exhaustive experimental investigation to discover the design that will best meet these requirements. And Victor engineers evolve the final apparatus and the method of making it.

Not yet is the task ended. The apparatus produced must withstand the searching test of actual practice in the hands of skilled physical therapeutists. Not until their approval is won does the medical profession hear of another Victor success.

HEALTH EDUCATION FROM THE VIEWPOINT OF THE PHYSICIAN

The proposed campaign of public health education will surely create a demand for new contacts between patient and physician. Physicians must give a new significance to the word patient, for in the new order of things both sick and well people must and will be recorded in the lists of their physicians. In one of his recent addresses, Dr. George E. Vincent has called attention to the demands which this newly informed public is likely to make.

"They will demand that their needs should be met," he has said, and he warns that unless the medical profession shall organize to meet the demand in the proper spirit, various forms of state medicine are likely to become the order of the day. "No thoughtful person can welcome the extension of state medicine beyond the legitimate and necessary field of public health activity, but if private initiative and voluntary cooperation fail, it may be impossible to resist the demand for governmental intervention" in the practice of medicine. In other words, the state may be called on to organize and control not only methods of medical treatment but also the financial remuneration of the physician. I believe that this is unnecessary, but it surely will come unless we ourselves give heed to the coming needs and formulate our modes and methods to meet this demand in the spirit of true medicine. For medical agitators to stand on the housetops and shout defiance to state medicine will never solve a problem which can only be solved by perfecting a better way. The better way is to promote by precept and example the vast importance of maintaining the personal relationship of physician and patient. This is an essential fundamental in medical practice. For this principle, which the medical men of wide vision are contending today, no brighter example can be named than the late Sir James Mackenzie. He was a far sighted student of mankind who devoted the later years of his life to preaching this beneficent gospel.

Wilson, a disciple of Mackenzie, in *Pygmalion, or the Doctor of the Future,* outlines a most vivid picture of the spirit of medicine advocated by Sir James Mackenzie, emphasizing that the intimate relationship of the coming medical man with his patient is to become more intimate than our present day leaders in medicine have demanded. "Once upon a time," he says, "the priest was the doctor," but, "tomorrow the doctor may well have become the priest, in a new sense of the word." Not deprecating the necessary scientific preparation for his calling, this physician of the future must be "a humanist, a man with the widest and deepest possible knowledge of human nature, and the profoundest possible understanding of human motives. He will be a cultured man, ripe in intellectual attainments, but not lacking in emotional sympathy, a lover of the arts as well as a student of sciences. This is, indeed, no more than a projection into the future of a gracious figure of the past—for the great physicians of other days were all, likewise, great citizens of humanity." There must be less of the machine or mechanical physician and more of the individual.

Our great leaders in medicine have emphasized fully the fact that this physician of the future, if he expects to meet the new demands in such a manner as to prevent the unfortunate entry into the practice of medicine of socalled state medicine, must prepare himself educationally, morally, psychologically and sociologically, to make the painstaking intimate personal contact with his individual patient so effective, outstanding and unassailable that no other form of medical practice will be permitted by the layman himself.

What have I described? No new word need be coined for the answer. The future health needs of the public can best be supplied by a more humane painstaking, better qualified, general practitioner of medicine. The family physician should remain the foundation of medical service. His outlook, functions and training need modification to meet changing needs. The field will be great and the opportunity for service boundless. The loyal service of the idea general practitioner of medicine will go far to limi the advent of insurance methods of treatment, stat systems, industrial groups, and other socialized prin ciples which the true psychologists and humanists i medicine look on as mechanistic, soulless, bureau cratic, card index systems, discounting the spirit o individual relationship characterized by the bette way.

The gospel of good health is based largely on th principles of preventive medicine. Our associatio endorses every proper method for promoting a phases of preventive medicine. Periodical examina tion of the apparently healthy is one of our project which promises well for the future as an importan agency for preservation of individual good healt The American Medical Association is pledged to thi measure, and state and county societies are rapidl becoming alive to its importance. Sufficient progres has already been made to demonstrate the fact tha many of the illnesses of life are unknown to the pa tient during the incipient stages. This procedu enables one's physician to detect the first danger si nal of any form of disease and to cope with it durir its incipient and curable stage.

This family physician must educate his patien and community in preventive medicine and be some extent a health administrator. His chief re and his chief service will be to keep his patients we Evidently, such service can be made possible only maintaining intimate, clinical information, well r corded, regarding every man, woman and child w seeks his service. And every man, woman and chi in every community should have his health record in the files of his family physician. Too many of o inhabitants worry through life with only fairly go health, and while they accomplish their daily duti these fairly well persons may never know the exub ance and happiness of perfect health. Hence, c goal of the future practitioner of medicine will the attainment and maintenance of exuberant heal which is the inherent right of every person. A hig average of overflowing good health means a hig average of happiness, comfort, usefulness and e nomic value of the individual. The superman v never materialize without superhealth.

THE EDUCATION OF THE FUTURE PHYSICIAN

Fundamentally, the business of the undergradu medical school is to teach scientific medicine. T application of the science of medicine on the part the physician constitutes the art of medicine, kno

WELCOME DALLAS To Our Exhibit A.M.A. April 19-23, 1926

Chicago the Center of Synthetic Medicinal Development in America

FIFTEEN years ago, the medical profession of the United States relied largely upon foreign sources of supply for its medicinal chemicals. Today these chemicals are made in America. Among the first firms in this country to manufacture many of these important medicinals, such as Barbital, Procaine, and Cinchophen, was The Abbott Laboratories.

Today, more Barbital, Cinchophen, Neocinchophen, Acriflavine and Neutral Acriflavine are manufactured by The Abbott Laboratories than by any other firm in America.

The Dakin chlorine synthetic antiseptics, Chlorazene, Dichloramine-T, and Chlorcosane were first made in this country by The Abbott Laboratories.

In addition to these, such other new synthetics as Butyn, Butesin Picrate, Benzyl Fumarate, Metaphen and Potassium Bismuth Tartrate have been developed in the Research Departments of The Abbott Laboratories, and the Dermatological Research Laboratories, and are manufactured by them.

The Dermatological Research Laboratories, the first and largest producers of Arsphenamines in the United States, was purchased by The Abbott Laboratories in 1922.

Thus does Chicago become the center of the synthetic medicinal development in America.

edge of which should be supplied by the undergraduate curriculum. At the outset it should be clearly affirmed with the fullest emphasis that the practice of medicine is in no wise a business, and those who purpose to enter this field of service should remember that their material interests must always remain a secondary consideration and that its emoluments may never be reckoned in terms of finance. The education of the physician of the future must provide instruction in the art of medicine as well as in the science of medicine—not less of the science, but more of the art is the educational need of the hour.

This view of medical education of the physician presages the future output of medical men whose scientific thinking will smack less of the mechanical, less of the technic of the laboratory, and more in the terms of the humanist. He must be taught to think more in terms of life, health and humanity than of disease and death. The medical education of the present places too much emphasis on the material and too little on the spiritual phases of medical practice. The student of medicine must be taught how to care for and advise the man as well as the patient. To this end, nothing need be done to disturb the high standards of medical education which the American Medical Association has set. It is necessary, however, that greater elasticity be given through proper modification of the present curriculum and policies of medical education.

The student should come in contact in the ambulatory department and at the bedside with patients for selfstudy under proper guidance and control. His course should include neurology, psychiatry, dermatology and the study of the diseases of children. It should also include instruction on the principles of both general and special surgery. A reasonable time should be devoted to ophthalmology, to otolaryngology, and to genitourinary and other special diseases.

I find myself in agreement with Billings that the ideal general practitioner "must have a good knowledge of general and physiological chemistry, of human anatomy and physiology, of pharmacology, of general pathology with constant training through the four years of residence in morbid anatomy, of epidemiology, immunology and psychology. In the clinical branches he must have the training of his brain, special senses and hands in the recognition of disease. He must learn to use the simple diagnostic aids in the form of instruments and laboratory tests. With this knowledge of the methods of diagnosis, he must have constant and daily opportunity to study disease as expressed in the ambulatory and ward patients. He must have an opportunity to observe the etiological relations of occupations, environment, social conditions and other factors in disease. He must learn and recognize the importance of community as well as individual disease. He must have the opportunity to observe the results of medical treatment and management and the final condition of the patient after operative surgery. He must have an opportunity to witness minor surgical operations, emergency surgery, and especially to have practical training in the treatment of fractures of the bones and dislocations." In the hospital he should have an opportunity for the practical study of dietetics and of dietotherapy. He should have practical experience in the measures of disinfection in the sickroom and especially in the control of communicable diseases. "Finally, in addition to the educational qualifications, both academic and medical, the family physician must be a man of character. His daily life must be a practical expression of honesty, morality and resourcefulness in service to his patients. He will have a due consideration of his own health and responsibilities, and at proper periods will play as he works with well directed energy, giving and asking half the road and fair play."

That these changes in the curriculum may be brought about, influence should be brought to bear on the state licensing boards to abolish the nonsensical requirement of a stated number of hours of study in each branch of the curriculum. Obviously, a four year course of study of medicine, preclinical and clinical, is not too long, particularly in view of the fact that every student should receive additional common sense instruction in public health, preventive medicine, psychology and sociology so far as the term applies to the necessary alliance of medical and social sciences in the prevention and palliation of disease.

Every undergraduate medical school should make the necessary changes in the undergraduate curriculum to provide for these additional subjects. The curriculum should further provide instruction in principles of professional conduct and the highest ideals of medical ethics.

If our future practitioner fails in these things, his "place in the sun" will progressively diminish and his rôle will be invaded by industrial, state and various group practices which will be a great disadvantage to our inhabitants. The family physician should remain the foundation of medical service.

In view of these added requirements in the education of the future physician, it is unthinkable even to contemplate any lowering of the standards of medical education. Nor should a limited medical training be approved for men who might be willing to practise in rural communities. Any claim for a limited medical training is fallacious in reasoning and untenable, for the reason that the best in medical care is none too good for our lowliest inhabitants, no matter where they reside. It is sometimes argued that physicians of mature years, graduates of a former generation, have been successful even though the educational requirements of that day covered not more than two or three years. But it must be remembered that this was the full medical education for its day, and the graduates of that day have reached distinction in the profession and have made valuable contributions to medicine, surgery and pathology, not because of their limited medical education, but in spite of those limitations.

It is true that in certain limited areas in our land there is some scarcity of physicians. It is also a fact that for some years, particularly during the World War period, fewer men entered the medical schools; but soon after the war the numbers began to increase, and, according to the report of the Council on Medical Education and Hospitals of the American Medical Association, the higher entrance requirements are not preventing students from entering the field of medicine. The total enrolment of medical students in the United States since 1919 has

Personal

WILL THE PHYSICIAN whose patient is suffering from kidney trouble please get in touch with the writer of this advertisement. He will learn something of decided advantage to his patient and himself by addressing—NEPHRITIN.

TO THE DOCTOR who has been puzzled as to the best means of overcoming that difficult case of chronic constipation, please communicate at once with —PANCROBILIN. A list of references as to ability will be cheerfully furnished.

TO PHYSICIANS—I have a proven record of success behind me and now seek a position as your assistant. I specialize on anæmic and "below par" patients. I am able to restore their vim, vigor and vitality. I will be glad to demonstrate results before you employ me steadily. Address—PROTONUCLEIN.

EVERY DOCTOR MUST have a vehicle. Bitter drugs, objectionable tasting medicines, become acceptable to the patient when I am used. I am a vehicle par excellence and have yet to meet a case where my camouflage screen has failed to produce the desired effect. I specialize particularly with children and can make your work easy for you. You may employ me for very small cost.—PEPTENZYME ELIXIR.

WANTED. The names of physicians who have difficulty in finding an efficient liquid food for ill and convalescent patients. I am it. I arouse appetite. I give strength. I am a tonic and nutritive food. My name and address is TROPHONINE, care of Reed & Carnrick.

The above advertisement is reproduced from the March issue of the R & C Medical Pocket Quarterly. Have you received your copy?

Reed & Carnrick, Jersey City, N. J.

increased at the rate of about one thousand a year, and in 1925 the approximate total enrollment of medical students in this country was 18,368. The proportion of students who are either partially or wholly selfsupporting during their medical course is as large now as it was in the former days. Furthermore, the majority of the medical schools of the country are never able to accept all the students who clamor for admission. Possibly a larger number of medical schools should be provided in order to educate the number necessary to meet the needs of communities.

In view of the great expense involved in the maintenance of our medical schools, and in view of the fact that a large proportion of this expense is a contribution from philanthropic sources, every school should enroll the largest possible number of students. No school should reduce its enrollment to less than fifty students in a class, and the larger and better equipped schools should increase the number further to at least eighty or ninety to a class. Furthermore, the undergraduate medical school should limit its teaching to the output of all round qualified general practitioners of medicine only, and it should in no sense attempt to prepare men for the various specialties. Preparation for all the specialties should be entirely dependent on graduate schools of medicine. So far as our country is concerned, courses for specializing may be secured through graduate medical teachings in the universities and postgraduate schools. The courses for the majority of the specialties should cover a period of at least three years. In several of the specialties in this country, particularly the eye, ear, nose and throat, examination boards have been created for men who desire to be formally recognized by the national societies. Fortunately, it is no longer necessary for men to seek the graduate training in foreign countries. Under this scheme of education, every specialist must first receive the preliminary training required by the general practitioner of medicine.

Careful estimates would indicate that properly qualified general practitioners of medicine, aided by moderate home laboratory facilities, will be able to make a correct diagnosis and give all necessary instruction and treatment to at least eighty per cent. of all the people who seek his aid, while twenty per cent. of specialists, including internists and general surgeons, all thoroughly educated and trained, will be ample in number to care for the sick who need highly specialized service. Furthermore, the same proportion will to a large extent hold true of those who require hospital and special laboratory service.

Regarding the distribution of physicians throughout the country, it is a fact that the urban population has rapidly increased and now is in excess of the rural. This proportion of the general population is emphasized to a greater degree in the distribution of physicians. There are various explanations of this fact, the chief of which are the advent of the automobile and better living conditions, educational, social and otherwise, in the larger towns. "The properly trained and educated young general practitioner, the product of the medical school which has made its curriculum elastic and modified to make a practitioner, will be fit to practice in either the city or the country. To induce him to go to the country will require improvement in social and educational opportunity in rural districts. This is rapidly coming about, but needs stimulation through cooperative endeavor from the medical profession, educators of the country and other agencies who will bring about better schools and facilities for social enjoyment."

NEED OF HOSPITALS

Time will permit only a brief mention of the hospital as a necessary facility in medical practice. At present, twenty-five per cent. or less of the practitioners, both city and country, have hospital facilities. Hospitals or similar facilities for the application of the refinements in diagnosis and treatment should be available in all communities, and particularly in rural districts. At present it seems somewhat difficult to supply proper hospital facilities in many rural communities, but our proposed extensive program of public health education should lead the enlightened laity to meet this demand. Every physician should be in contact with hospital facilities and experience—his progress in his profession depends on it. In every instance, particularly in rural communities, open staff organizations are preferred; but hospitals connected with medical schools must necessarily be closed staff organizations. It is possible that in other hospitals the open staff organization could be made practicable by having a socalled executive staff or regular attendants in all departments who would be responsible for the character of the professional conduct of the hospital, and this staff would be supplemented by an auxiliary or associated staff properly classified and made associate members of the executive staff departments. This would afford every worthy physician of the community a hospital connection, but he would be obliged to follow the regulations of the hospital made and adopted by the executive staff.

CONCLUSIONS

May I venture the following conclusions and opinions:

The scheme of undergraduate medical education should be reconstructed to include in its curriculum as a prominent feature the science and art of health conservation, and the art of applying the principles of the science of medicine through the personal relationship of the physician and his patient. The undergraduate student must be trained to treat the body from the viewpoint of health as well as that of disease.

These added requirements to the educational program of the future physician emphasize the argument against any lowering of the standards of medical education or lessening of the time involved in the teaching process.

Public health education is an outstanding need of the hour. The gospel of personal and community health is complex. It should be promulgated by health departments and agencies, by lectures, radio and film; but it will never reach its highest efficiency until it includes a maximum of direct personal instruction by properly qualified family physicians.

The patient of the future, in view of his perfected health education, may be expected to derive from it a wise judgment which will lead him to seek the continued advice and counsel of his personal physician. Furthermore, in view of our perfected

RAYMINOL (DOYLE)

Restoration *of* Function

should be the purpose of any agent given in the presence of constipation or irregular bowel action.

In pursuit of this purpose—RESTORATION OF LOST BOWEL FUNCTION—RAYMINOL (DOYLE) IS A LOGICAL AGENT. It is a scientific combination of liquid petrolatum and aromatized rhubarb to which has been added a pancreatic extract from the whole gland and phenolphthalein.

NO AGAR CONTENT

In autointoxication, sluggishness of bowel function or frank constipation RAYMINOL (Doyle) will meet your demands for its use is toward the restoration of function.

system of individual and community health education, cults and other menaces to public health, all of which are founded on theories for the most part baseless and futile, will gradually disappear before the rising sun of enlightened public opinion.

The ideal family physician of the future by training, by experience, and by expert knowledge of health conservation will derive a potential power which will qualify him to control and direct the health problems of men.

The family physician of the future must have proportionate representation in the councils of his profession. No specialty or combination of specialties, not even general surgery, should be permitted to dominate the health affairs of a community or of a nation.

It is true that the service rendered by a physician may not be considered in terms of finance, but in no sense should our physician of the future offer this as an excuse for slothfulness in the management of his business affairs. Every detail of his newer service in the prevention of disease is of great value to his patient. Health education and conservation are services of value even greater to the patient than the sums paid for helping the body to repair the ravages of disease.

The maintenance of individual practice in the person of the general practitioner or family physician is of the utmost importance for the survival and continuation of the family home as the foundation of the nation.

Finally, let us hope that the physician of the future will be fully conscious of the vastness of the causes which he must advocate and the usefulness of the deeds he must accomplish; that he may have wisdom, poise and capacity of understanding that will breed in his patient an extraordinary confidence and esteem; that he may have a vision of a healthier, happier world which will blossom into unheard of activity. May we hope that to this end he will dedicate himself "through service to all that will advance and maintain and increase the sum of human happiness."

Every man who looks toward the future is charged with being a dreamer. But the verdict of history has always been that the onward march of science, religion and civilization has been led by dreamers. I have ventured modestly to tell my dream, knowing that it will find a thousand responsive chords in the hearts of my colleagues whose ambition and passion are to serve our fellowmen.

Who dreams shall live. And if we do not dream
Then we shall build no temple into time.
Yon dust cloud, whirling slow against the sun,
Was yesterday's cathedral, stirred to gold
By heedless footsteps of a passing world.
The faiths of stone and steel are failed of proof,
The king who made religion of a sword
Passes, and is forgotten in a day.
The crown he wore rots at a lily's root,
The rose unfurls her banners o'er his dust.
The dreamer dies, but never dies the dream.
Though Death shall call the whirlwind to his aid.
Enlist men's passions, trick their hearts with hate,
Still shall the vision live. Say nevermore
That dreams are fragile things. What else endures
Of all this broken world save only dreams!
—*Dana Burnet.*

The Scientific Proceedings

We present below abstracts of some of the more important papers read at the various section meetings. The publication of these abstracts will be continued in future issues of the JOURNAL.

SECTION ON PRACTICE OF MEDICINE

CHAIRMAN, DR. E. S. KILGORE, OF SAN FRANCISCO.
SECRETARY, DR. BRYCE W. FONTAINE, OF MEMPHIS, TENN.

Method of Following Treatment in Diabetes.—Dr. Rollin T. Woodyatt, of Chicago, said that in following cases of diabetes one wishes to follow the variations of the patient's power to utilize glucose. If at one time he is capable of utilizing 150 grams per twenty-four hours and at a later time 120 grams, his sugar using function has decreased, and so forth. If a given individual on a certain day receives from all sources the equivalent of 150 grams of glucose and eliminates 50, he utilizes the difference or 100 grams for the day. If he receives the equivalent of 200 grams and excretes 50 he utilizes 150. What we wish to know is how many grams of glucose per unit of body weight per unit of time the patient can utilize, i. e., the rate of glucose utilization.

The question arises as to how we may measure the rate of glucose utilization in diabetic patients under clinical care in the most practical way. The percentage of sugar in the urine taken by itself gives no index. The total quantity excreted in the day taken by itself is of little more value. The difference between the rate of supply and the rate of excretion is, however, an absolute index.

There is a certain parallelism between variations of the rate of utilization of sugar and the blood sugar concentration. However, the relationship between the blood sugar concentration and the rate of glucose utilization is subject to more or less variation. Measurement of the total excretion of sugar in the urine by a method such as that of Folin and Berglund for the quantitative estimation of sugar in the normal urine, taken in conjunction with knowledge of the diet offers an easier, cheaper and in the main more exact method of following variations of the glucose using power than any other available method. The total output for a given period of time tends to vary as the *average* blood sugar percentage during that entire time. But to find the average blood sugar percentage by direct readings requires multiple punctures of the patient and multiple analyses, entailing extra work, expense and discomfort. The same information is obtainable by uranalysis (if the method of analysis is sufficiently exact), cheaper, with less discomfort to the patient, and withal more accurately, since the figure obtained in the urine is an aggregate for all of the hours of the period during which the specimen was collected.

The paper presented experiments and clinical data showing the theoretical and practical advantages of following cases by diet and urine rather than blood data.

ALPHA-LOBELIN
INGELHEIM

"The Hypodermic Pulmotor"

Acting as a direct stimulant to the respiratory center, Alpha-Lobelin is indicated in respiratory depression or failure resulting from shock, drowning, gas and drug poisoning, anesthesia accidents and Asphyxia Neonatorum.

Activin

The ideal agent for use in non-specific foreign protein therapy. Effective in doses of one half to one cubic centimeter without causing a severe general reaction.

Anayodin

(*Iodoxyquinolinsulphonic acid*)

In the treatment of Amebic Dysentery this active amebacide is enhanced in value by the healing influence which it exerts on lesions of the intestinal mucosa.

It may be administered orally in pills and capsules or a solution in enemata.

Diatussin

Its almost specific action in Whooping Cough is shown by the marked decrease in severity and number of paroxysms during the first twenty-four hours of treatment.

Its ameliorative influence in other spasmodic coughs is also very pronounced and gratifying.

Descriptive literature on request.

ERNST BISCHOFF CO., Inc.

133 Hudson St. **New York**

Chronic and Recurrent Bronchitis Simulating Tuberculosis.—Dr. Charles N. Meader of Denver, Colo., said that there existed a type of mild, subacute nontuberculous peribronchitis, which might produce interference with the patient's comfort and economic efficiency wholly out of proportion to the physical signs detectable on casual examination. It was to be compared with and differentiated from occult tuberculosis, which might produce closely similar symptoms and signs. Such differentiation could usually be made, but only by careful study and evaluation of the whole clinical picture, including x ray findings and specific tests. It was important that these conditions be recognized and differentiated, because they were capable of much relief; tended, if untreated, to the development of more marked and serious involvement; offered materially different prognoses as to the patient's probable future limitations; and responded to materially different forms of treatment.

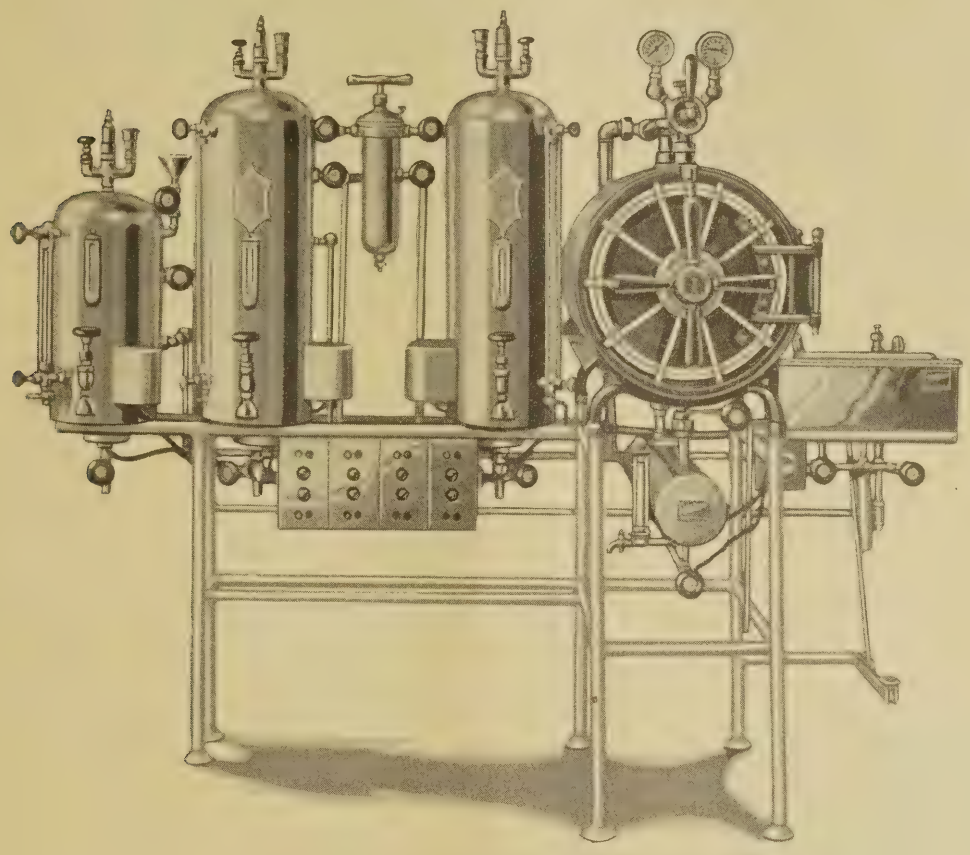
Some Unique Features of Hodgkin's Disease (Lymphogranulomatosis): Clinical and Autopsy Studies.—Dr. Moses Barron, of Minneapolis, Minn., stated that Hodgkin's disease was an anatomical and clinical entity, an infectious granuloma, probably caused by an animal parasite. Absolute diagnosis was possible only by biopsy. Extensive caseation necrosis was sometimes present, which might cause confusion in differential diagnosis from tuberculosis. The symptoms were described. The average duration of the condition was less than two years, and the prognosis was hopeless. Severe secondary anemia was invariable in late stages. Blood picture was not always characteristic. Eosinophilia was frequently present. Disease usually began in lymph nodes, and might invade all tissues and organs. Involvement of vertebræ sometimes caused confusion with Pott's disease. It was sometimes associated with tuberculosis, but tubercle bacillus bore no etiological relationship to the disease; neither did the diphtheroid bacillus nor Bacillus Hodgkini. The disease occurred most frequently during the second and third decades, occurring oftenest in males. In discussing treatment, the x ray he said might cause temporary improvement in symptoms, but did not affect the progress of the disease. Hodgkin's disease with the chronic relapsing type of fever presented one of the most remarkable syndromes in medicine. Three cases were reported, with autopsy study in twenty-four cases.

Rheumatic Pneumonia.—Dr. Meyer A. Rabinowitz, of Brooklyn, N. Y., presented a study of a recent series of cases of acute articular rheumatism and acute rheumatic affection of the heart with special reference to the occurrence of pulmonary manifestations. He reported a group of cases occurring early in the severer types of rheumatic fever without crisis, marked dullness, scant râles and loud bronchial breathing. The posterior areas of chest were usually involved, he said. The prognosis was excellent *per se*. He described a type not conforming to the usual pictures of embolic enfarction, pulmonary edema, atalectasis due to pericardial or plural effusion, bronchopneumonia or croupous pneumonia. Is there a true pneumonia, he asked, due to rheumatic virus? Are these lung lesions not specific in nature but dependent on cardiac dilatation and insufficiency? Splenization of the lung as a clinical entity, was discussed, its etiology, pathology, symptoms, and differential diagnosis.

Precordial Pain.—Dr. Eugene S. Kilgore, of San Francisco, Cal., in his chairman's address, said that the analysis of a group of office patients complaining of pain about the heart or sternum showed a large preponderance of cases which were not true angina pectoris, and that this study concerned itself mainly with the diagnosis of what might still profitably be termed "pseudoangina." Various types of this pain are observed, the most common having a stabbing or piercing quality. All gradations of this type of pain occur, from the common "stitch in the side," which most persons have felt, to what some patients describe as terrific pain "like a stroke of lightning through the heart." He said that among the causes of pseudoangina, psychic trauma played an important rôle. This is often administered by the well meaning but unskillful doctor, who fails to recognize the innocent character of the symptom. The author believes that the practical application of the result of the study is a plea for better initial diagnoses and more careful psychic handling of these cases.

Practical Considerations of Renal Physiology and Function.—Dr. Philip S. Hench, of Rochester, Minn., said that a concise understanding of renal physiology and its relation to its function was of importance in the management of chronic nephritis. The functions of the kidney could be readily outlined. Regarding renal physiology, however, apparently contradictory evidence had resulted in various theories of the *modus operandi*. A brief survey was useful to differentiate such knowledge of practical importance to clinical medicine from that of less direct or only theoretical bearing. The four established functions of the kidney were, 1, the excretion of certain nonvolatile end products of metabolism: urea, uric acid, etc.; 2, the regulation of the body economy for water and salt; 3, maintenance of the acid base equilibrium of the body; and 4, the synthesis of hippuric acid and possibly some urinary ammonia.

The two main thories of renal physiology was the "vital" theory of Bowman and Haidenhain and the "mechanistic" theory of Ludwig. The "modern" theory of Cushny had in part been supported by the work of recent investigators, notably Starling and Verney, Richards, and Marshall and Crane. Summarizing the various theories would lead to the present acceptance of the belief that a mechanical filtration of a protein free fluid occurred through the glomeruli. This filtrate was further elaborated into the urine by the action of tubules through a process of reabsorption alone, or of reabsorption plus active secretion. The author remarked that physiological data can not always be brought into direct relationship with pathological findings in nephritis. Although confusion may result from an attempt to correlate physiological conceptions, clinical syndromes and pathological data, the clinician can from the viewpoint of practice honestly sidestep such confusion by a consideration purely of the clinical picture. By the use of a few simple clinical observations and a few readily available laboratory procedures, a sufficiently correct differentiation of the type of renal lesion



Something Entirely New

in electrical sterilizers is shown in the Kny-Scheerer Corporation's exhibit, Space No. 205 at A. M. A. Convention, Dallas, Tex. The new thermostatic controls for dressing and water sterilizers automatically cut out the current when sterilizers need water irrespective of pressure on same. They also automatically cut out the current when the pressure reaches 19 pounds, and automatically cut current in when pressure goes down to 17 pounds. To start the sterilizers, one merely presses a button—to stop, another button.

Stop at Booth No. 205 *and ask our salesmen to demonstrate this sterilizer for you.*

119 Seventh Avenue Dept. "L" New York, N.Y.

present can be attained, and with it direct indications for treatment and prognosis.

Albuminuria, though the earliest, most readily detected aberration of normal renal function, is present in about five per cent. of apparently healthy people. The differentiation of significant and insignificant albuminurias is of prime importance and can be done only by a careful analysis of readily available clinical and laboratory data.

Volhard and Fahr's classification of nephritis was advocated and compared to others. The four main types of chronic renal lesions were, 1, chronic glomerular nephritis, associated with urinary findings of albumin, casts, erythrocytes, with nitrogen retention in the blood, with changes in blood pressure, eye grounds, heart, and blood count; 2, chronic nephrosis, associated mainly with albuminuria and edema and without systemic changes; 3, chronic focal nephritis, characterized by erythrocytes, albumin and casts in the urine without nitrogen retention or systemic body changes, and 4, arteriosclerotic nephritis, a more or less incidental finding eventually manifesting itself by a moderate albuminuria, a slight degree of nitrogen or dye retention and slowly progressive and comparatively benign renal insufficiency.

These forms may be differentiated by clinical findings and the use of five simple tests: 1, the phenolsulphonephthalein test; 2, water, dilution, test; 3, concentration test; 4, the determination of urea retention by means of the estimation of the mercury combining power of blood or of saliva—the salivary urea index; and 5, the hemoglobin and the erythrocyte count.

The author stated that the determination of the mercury combining power of blood or saliva were new tests which may be readily made within ten or fifteen minutes with a minimum of laboratory apparatus and gave the same information as the determination of blood urea. Prognostic information may also be obtained by certain clinical observations and these simple function tests. Scientific therapy depended upon the recognition of the types of functional disturbance present. Although clinical classifications may not be clear in individual cases and may have to be disregarded, functional classification must be attempted. Principles and methods of treatment were outlined in some detail. These included the use of certain new diuretics with which therapeutic successes heretofore unattainable have been obtained.

SECTION ON SURGERY, GENERAL AND ABDOMINAL

CHAIRMAN, DR. DALLAS B. PHEMISTER, OF CHICAGO.
SECRETARY, DR. J. TATE MASON, OF SEATTLE.

The Interrelation of Lesions of Bone Marrow, Liver, and Spleen.—Dr. William J. Mayo, of Rochester, Minnesota, said:

Fairly accurate knowledge of the structure of the cellular elements of the blood has been gained through the microscope, but the constituents of the plasma lie in the colloid and molecular fields beyond microscopic observation. Fortunately great additions have been made to scientific data through newer work in physiochemistry, by which the ultramicroscopic field has been presented in such form that we can better elucidate its many problems. In photography a method has been perfected of fixing movements of particulate bodies which are too small or in too rapid motion for the eye to take cognizance of them.

The red blood cells are the oxygen carriers of the body and are formed in the bone marrow; the blood platelets are formed in the megakaryocytes of the bone marrow and have to do with the clotting of the blood; the white blood cells are formed in the reticuloendothelial tissues and have properties of repair and defense. In the normal blood the hemoglobin carries from 18.5 to 20 per cent. of oxygen by volume, in loose combination.

In pernicious anemia the patient is unable to produce normal red blood cells.

In polycythemia, there is an enormous increase in red cells, and a great development of the hemoglobin. The consequent increase in the viscosity of the blood adds to the work of the heart, and often results in cardiac hypertrophy and eventually muscle failure, of the type seen in cases of grave hypertension.

In hemolytic icterus the production of the red blood cells is increased, probably a work hypertrophy to attempt to compensate for the unnecessary destruction of red cells in the spleen. In hemorrhagic purpura there is destruction of the blood platelets in the spleen with prolongation of the bleeding time. The blood clots, but the clot does not contract normally.

The liver is the great metabolic organ of the human body, and is essential for both carbohydrate and protein metabolism, as evidenced by Mann's work proving that the normal blood sugar level cannot be maintained, and urea is not formed without the liver. The work of the liver is done on venous blood which has a decreased oxygen content, and consequent slight power to metabolize fat. The blood plasma is largely formed in the liver.

The rate of elimination of dyes from the blood stream, when introduced intravenously, is in direct proportion to the size of the molecule of the dye, and has given much information as to the functions of the kidneys, the liver, and other organs.

One of the most important functions of the liver is the detoxication of chemical substances and the destruction of bacteria and protozoa.

The spleen is a hemolymph gland, and as such belongs to the reticuloendothelial system. Because it is only one of a large group of similar tissues, its removal causes little or no change in the functions of the body. While physiologically the spleen is not very important, pathologically it is extremely important.

The spleen also acts as a coarse filter to remove microorganisms from the blood stream. Those which it cannot destroy it sends ordinarily to the liver for destruction, sometimes resulting in portal cirrhosis. Often the spleen becomes a habitat for bacteria and protozoa which it is unable to destroy completely or send to the liver, and consequently gives rise to the reinfections so often seen in the splenomegalia of syphilis, malaria, and tuberculosis, manifested by chronic anemia and failure to respond to remedial agents.

Dr. Mayo appended to this paper a statistical review of 424 cases of splenectomy.

Results of Animal Experiments With Osteoperiosteal Bone Graft.—Dr. George M. Dorrance and Dr. George Wagoner, of Philadelphia, said that

THE SCHELLBERG APPARATUS

for use in Colonic Therapy

In treating the afflicted by colonic therapy the elimination of toxins alone will frequently work a marked change for the better, and when this is supplemented by the intelligent application of the drugs suited to meet the requirements of the individual case, it will be found the surest, as well as the most conservative, means of restoring the normal status throughout the body.

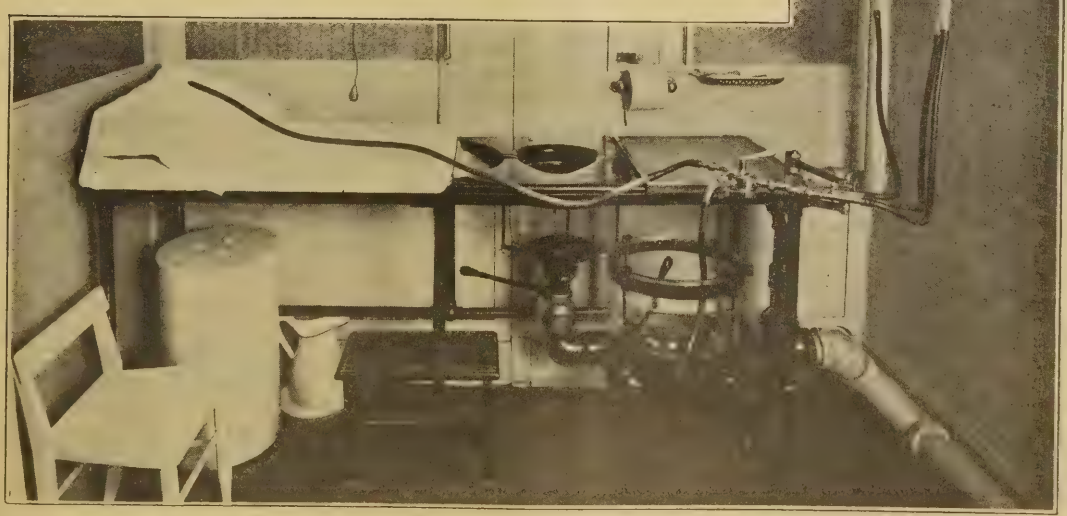
The apparatus is patented to prevent its exploitation by inexperienced and unauthorized persons, and is sold only to physicians.

Prospective purchasers are requested to write for information on their professional letter-head, or card.

The price of the apparatus is $400.00 complete—$325.00 without swing joint and bowl—F. O. B. New York.

THE SCHELLBERG MANUFACTURING CORPORATION

172 Chambers St. **New York, N. Y.**



clinical and experimental researches showed that it was possible to reproduce bone or to reunite an ununited fracture by means of an osteoperiosteal bone graft. The bone graft increased in size and thickness to conform to the surrounding bone. It was especially applicable where a curved surface or angle was necessary, as in the jaw or skull. Animal experimentations have proved it was possible to produce an extraarticular ankylosis by exposing the bone above the joint and the bone below the joint and connecting one incision to the other by undermining the skin. The graft was connected to the upper bone, then passed through the tunnel under the skin down to the bone below. This then was the extraarticular connection of the bone above to the bone below. The x ray showed that bony union had been produced.

The authors stated that while Albee's contention was that the full thickness graft will grow through a tuberculous area, it seemed unwise to open up an infected wound, and that by having the bone graft go around the joint, the same results would be obtained. They did not discuss whether a full thickness graft or periosteal was superior to the other, but asserted that they had separate indications and were almost interchangeable. The technic of the ostoperiosteal graft was simpler and did not require the armamentarium that the full thickness graft required. The particular issue was the production of ankylosis by the osteoperiosteal method.

Local Anesthesia as an Adjunct in the Treatment of Nontuberculous Lesions in Tuberculous Patients.—Dr. Stanley R. Maxeiner, of Minneapolis, Minn., said that patients suffering from tuberculosis were subject to the same general diseases that other people had. Careful gastrointestinal and x ray study often revealed a gastric or duodenal ulcer, cholecystitis, obscure appendicitis or painful visceroparietal adhesions. The author said that he had treated carcinoma of the lip, exophthalmic goitre, acute mastoiditis, and other conditions, and had performed for tuberculous and nontuberculous lesions more than two hundred major and minor operations under local anesthesia alone without a postoperative pneumonia or operative mortality.

SECTION ON OBSTETRICS, GYNECOLOGY, AND ABDOMINAL SURGERY

CHAIRMAN, DR. GEORGE GRAY WARD, OF NEW YORK.
SECRETARY, DR. CARL H. DAVIS, OF MILWAUKEE.

Chronic Endocervicitis, Its Etiology, Symptomatology and Secondary Pelvic Manifestations.—Dr. C. Jeff Miller, of New Orleans, said: No uniformly satisfactory treatment has as yet been found for endocervicitis, the commonest of all gynecological affections, due largely to the fact that the histology and pathology of the cervix are not sufficiently considered. These facts are stressed in this introductory paper, which is necessarily elementary. The comparative histology and function of the cervix and uterine body are considered, with emphasis on the fact that the complicated structure of the cervix makes it peculiarly fitted for the harboring of bacteria. The possible etiology includes specific and other infections, cervical lacerations, congenital erosions, and local and systemic conditions. Certain cases remain inexplicable. All types of bacteria are involved, the gonococcus being the most frequent. The pathology may include inflammatory changes, eversion, erosion, cystic formation and hypertrophy. The symptomatology may include leucorrhea, menstrual derangements, backache, dyspareunia, sterility, and pelvic and systemic manifestations. Diagnosis is usually simple but should always include laboratory studies. Cervical tuberculosis, syphilis and malignancy must be differentiated, as well as infections of the upper and lower genital tract. The cervix is a possible source of infection in systemic conditions, but the question is not yet settled. Any treatment to be successful must be based upon the underlying pathology of the deeper cervical structures.

Myomectomy, Hysterectomy, and Radium in the Treatment of Uterine Fibromyomata.—Dr. James C. Masson, of Rochester, Minn., said that symptomless fibromyomata demand no treatment. Radiotherapy is indicated in all patients, over forty years of age with fibromyomata under fifteen cm. in diameter when menorrhagia is the chief complaint; in patients under forty years of age when the patient refuses surgical removal or where there is some added risk to a major operation; and in all cases of *fibrosus uteri* or cases with essential hemorrhages. Surgery is indicated for fibromyomata, 1, in most patients under forty years of age; 2, in most patients where pain or bladder irritability is associated with fibromyomata; 3, in any patient in whom a tumor over 15 c.m. in diameter is present; 4, when a tumor is pedunculated, submucous or undergoing degeneration or inflammation; 5, when there is any doubt about the tumor being a fibromyoma; and 6, when any other indication for opening into the abdomen exists. Of the surgical cases, abdominal myomectomy should be the operation of choice for the majority of patients under forty years. Vaginal myomectomy is indicated if a fibromyoma is presenting through the cervix. Subtotal abdominal hysterectomy should only be performed in women under forty years when it is necessary to remove the greater part of the body of the uterus and when the cervix is in good condition. Total abdominal hysterectomy is the operation in the best interest of the patient when any pathology other than cancer exists in the cervix and an abdominal operation is advisable, and when the history suggests the possibility of malignant change in the fibromyomata or an associated malignant condition in the body of the uterus.

Pregnancy Complicating Exophthalmic Goitre and Adenomatous Goitre With Hyperthyroidism.—Dr. Robert D. Mussey, Dr. William A. Plummer, and Dr. Walter M. Boothby, of Rochester, Minn., said that since 1916 pregnancy has been observed at the Mayo Clinic in thirty-two patients having exophthalmic goitre and in ten having adenomatous goitre with hyperthyroidism. As the hyperthyroid states developed in all but two of the forty-two patients before the onset of pregnancy, their association seemed accidental. No maternal death occurred as a result of the hyperthyroid states. There were two spontaneous abortions and two premature labors apparently associated in large part with other complications. Therefore, the risk inherent in each of these conditions was not greatly increased. Either

The Mineral Balance of the Human Body

A Vital Factor in Health and Disease

Our Research Laboratory has compiled what is undoubtedly the first comprehensive brochure covering the importance of the Mineral Balance and the application of Mineralization in the treatment of disease.

This Brochure Will Be Sent Free of Charge to Every Physician upon Request

It tells of the new Mineralization Product

MINERASAL

which contains the thirteen Essential Mineral Elements of the human body in assimilable form and in the proportion in which they are found in the blood plasma and tissue.

MINERASAL is a granular effervescent product.

It makes a palatable drink, which is taken with relish by children and invalids.

It is a mineral food, to be used as an adjunct in the treatment of any condition where there is faulty metabolism or a need to reinforce the normal diet.

MINERASAL was originated by and is manufactured solely in the Laboratories of

G. D. SEARLE & COMPANY

ligation, thyroidectomy, or both were performed on thirty-four patients without mortality and since the introduction of iodine as an aid in the treatment of exophthalmic goitre, ligations were found unnecessary as a preliminary procedure to thyroidectomy. Therefore, when advisable for the control of exophthalmic goitre, or adenomatous goitre with hyperthyroidism, thyroidectomy can be carried out with proper precautions on the pregnant woman with reasonable safety to both mother and fetus.

Magnesium Sulphate Intravenously in the Treatment of Toxemia.—Dr. Lyle G. McNeile and Dr. John Vruwink, of Los Angeles, Cal., said that a ten per cent. solution of recrystallized magnesium sulphate, in doses of ten to twenty-five c.c., given intravenously, is a valuable adjunct in the prevention and care of eclampsia. Experimental and clinical medicine has demonstrated that magnesium sulphate inhibits nervous irritability; that, as a hypertonic solution it will decrease cerebrospinal fluid pressure and reduce brain bulk; and that it has anesthetic properties. It is our experience, the authors said, that it also decreases the congestion and swelling of the kidney and aids in elimination. A series of cases so treated at the Los Angeles General Hospital had given better results than all previous methods of management.

Eclampsia at the Chicago Lyingin Hospital: Immediate and Late Results.—Dr. J. P. Greenhill, of Chicago, Ill., said that during the last eight and one half years, seventy-eight cases of eclampsia were treated at the Chicago Lyingin Hospital. Among these seventy-eight cases there were six maternal deaths, an incidence of 7.7 per cent. If one moribund untreated case was deducted the mortality would be 6.5 per cent. In fifty per cent. the convulsions began before labor, in 20.5 per cent. during labor and in 29.5 per cent. after delivery. The maternal mortality for these groups was 10.3 per cent., 0 per cent., and 8.7 per cent. respectively, and the fetal mortality was forty-one per cent., 18.8 per cent., and 17.4 per cent. respectively. The incidence of operative deliveries was 62.5 per cent. However, while 36.3 per cent. of all the labors terminated spontaneously, labor had been induced in 11.3 per cent. of them. Hence, only twenty-five per cent. of the cases had both a spontaneous onset and spontaneous termination of labor. Convulsions ceased after delivery in 78.2 per cent. of all the cases where they began antepartum or intrapartum. Among the fifteen abdominal Cæsarean sections convulsions began before operation in twelve, and in all of these cases the convulsions ceased after operation.

The maternal mortality for the various forms of delivery was as follows: Spontaneous 3.4 per cent., Cæsarean section 6.7 per cent., forceps 9.5 per cent. and version and extraction 14.3 per cent. The fetal mortality for these groups was as follows: Forceps 9.5 per cent., abdominal Cæsarean section 17.6 per cent., version and extraction 28.6 per cent., spontaneous thirty per cent., and vaginal Cæsarean section 100 per cent. Among the seventy-eight patients, fifty-nine per cent. had no prenatal care at all, twenty-three per cent. had very poor observation during pregnancy and eighteen per cent. had good prenatal care.

There were five pairs of twins, 6.4 per cent. Among the eighty-three babies there were twenty-three deaths (27.7 per cent.). However, the fetal mortality of the seventy-five babies that were alive when their mothers entered the hospital was only twenty per cent. Of the fifteen dead babies which constituted this twenty per cent. only one weighed more than two thousand grams, four pounds seven ounces. Only 62.7 per cent. of the babies weighed two thousand grams or more.

Of the 72 patients who left the hospital alive, sixty, 83.3 per cent., were traced. Of this number two died of chronic nephritis, three now have chronic nephritis and fifty-five, 91.7 per cent., are well. Among eighteen subsequent pregnancies ten ended normally and one was in progress now. One patient had another attack of eclampsia and three had pre-eclamptic symptoms for which the pregnancies were ended. Hence, among the patients who completely recovered after the attack of eclampsia of those who subsequently became pregnant, 26.7 per cent. presented signs and symptoms of toxemia. These patients again recovered completely.

As a result of this study the author thought that the treatment of antepartum and intrapartum eclampsia should not be entirely conservative nor entirely radical. However, in experienced hands he favored emptying the uterus in most cases, and the method selected, he said, depended upon the condition of the patient, the size of the baby and the state of the cervix. Where the patient was a primipara with a viable baby and the cervix was undilated, he preferred to terminate pregnancy by a low or cervical Cæsarean section under local anesthesia as soon after the first convulsion as possible. He believed that all patients with eclampsia should be sent to a hospital. When a patient must remain at home the treatment should be conservative. It should also be conservative in a hospital when the attending physician was not skilled in operative obstetrics.

Radium in the Treatment of Cancer of the Cervix Uteri.—Dr. Grant E. Ward, of Baltimore, said that the purpose of his paper was twofold. First, to describe the technic for treatment of cancers of the cervix developed at the Howard A. Kelly Hospital in the last eighteen years' experience with radium. This description will include the apparatus used and the principles underlying the technic employed. The second aim of the paper is to review briefly a few statistics from other clinics, and to compare former statistics with a new series which has just been studied. This new series includes those cases treated in the years 1921 and 1922. This group comprises in all 231 cases. A brief review of the cases in this series follows: In the fourteen operable cases treated by radium alone, eight patients have remained well from eight months to four and a half years. In the socalled borderline group, which were really inoperable, four patients out of nineteen were well from two to four years; one recurred after five years. In over fifty per cent. the local lesions were healed. In the cases recurrent after panhysterectomy, forty-one in number, ten patients, or twenty-five per cent., remained well from two months to five years. In the inoperable group, of which there were 141, sixteen showed no evidence of disease when last

It meets the dictates of modern medical practice

KELLOGG'S ALL-BRAN is most widely employed to relieve constipation — but it is equally valuable in **preventing** constipation and promoting regular, natural elimination of the intestinal tract. Preventive medicine of the highest order!

Physicians recognize in Kellogg's ALL-BRAN a valuable aid and ally in combating the evil of constipation. They know that Kellogg's is 100% bran and for that reason they can rely upon its accomplishing definite, complete results. That is why ALL-BRAN is recommended by so many of the profession in both mild and chronic cases.

Patients like Kellogg's ALL-BRAN and like to "take it." Kellogg's is cooked and krumbled by a special process that gives it a delicious, nut-like flavor. A delightful breakfast dish. There are countless appetizing ways of serving it.

Sold by all grocers. Served everywhere. Made by Kellogg in Battle Creek, Michigan.

Look for this signature W. K. Kellogg

seen. Of the 125 remaining, 101 showed improvement or healing in the local growth. By improvement is meant symptomatically as well as on physical examination. In the 125 inoperable cases which were not cured, twenty-one patients lived from two to four years.

Other groups, such as prophylactic after operation, and those treated by combining radium with cautery, were also discussed.

Cauterization vs. the Sturmdorf Operation in the Treatment of Chronic Endocervicitis.—Dr. Harvey B. Matthews, of Brooklyn, N. Y., said that chronic endocervicitis was the most common pelvic disorder that the gynecologist or general practitioner was called upon to treat. Practically every multiparous and many nulliparous women suffered from more or less leucorrhoeal discharge which was cervical in origin. He said that it had been proved without doubt that chronic endocervicitis was a very prevalent disease; while chronic endometritis, as a pathological entity, was very rarely encountered. Endocervicitis may be acute or chronic. In most instances, when first seen by the physician, the inflammation has already passed from the acute into the subacute or chronic stage, usually chronic. The endocervical mucosa, with its compound racemose glands, offer an ideal nidus for the propagation of bacteria. Once pathogenic bacteria are planted in this situation the resulting inflammatory process becomes very difficult to manage. In fact it was only by eradicating the foci of infection located in the cervical mucous membrane and adjacent cervical glands, often extending from the external to the internal os, that the leucorrheal discharge, backache, bearing down sensation, etc., were relieved. When marked hyperplasia and cystic formation, Nabothian cysts, were present the problem of cure was still more difficult. Furthermore, the author believed the longer the infection remained *in situ* the deeper and wider it disseminated into the endocervical mucous membrane and its glands. He said it would seem, therefore, that the earlier treatment was begun after the infection was implanted the more certain would be the cure. The treatment of chronic endocervicitis was prophylactic and operative.

Under the prophylactic treatment, the author wished only to consider the use of the cautery. Naturally there were many nonoperative methods of treating the infected cervix but which do not come up for consideration at this time. By the judicious use of the small nasal cautery the superficial infection, with eversion and erosion that was so frequently seen ten to twelve weeks postpartum, could be made to heal and "roll in" in three to six weeks. This was accomplished by making several linear incisions, spaced one half to one cm. apart and four to six mm. deep, made over the erosion on the anterior and posterior lips of the cervix and extending well into the canal. The cauterization, if necessary, may be repeated in two weeks. He said that this method of treatment will stop the leucorrheal discharge in almost all cases and the patient will continue very comfortable until the next baby comes along and then the same treatment must be carried out again. The deeply infected, hyperplastic cystic cervix of long standing may be cauterized by using the same technic but by going deeper, wider and further up the cervical canal, up to or near the internal os, with the cautery. The results in these types of cases were not as good as in the more superficially infected type. In these cases, also, stricture or stenosis of the canal with subsequent hematometra must be guarded against. Complete destruction of the endocervical mucosa will surely result in stenosis. Strips or elongated islands of mucous membrane must be left in order for epithelialization to take place with consequent preservation of the cervical canal. Anesthesia may or may not be used for this type of cauterization, depending on the extent of the lesion and amount of cauterization required.

The Sturmdorf operation was designed to remove the infected foci from the cervical canal without taking any or but very little of the cervical body away. When done properly, he said, it was the best means of accomplishing this end. It was not an amputation and should not be so called. It was an excision of the infected mucous membrane substituting noninfected mucous membrane for infected. It does not interfere with pregnancy or labor any more than trachelorrhaphy, which is practically nil.

In comparing the efficacy of these two methods of treatment of chronic endocervicitis, it would seem fair to state that cauterization was indicated in all superficially infected, moderately eroded and everted, not too extensively lacerated cervices that should have something done but which were not sufficiently severe to warrant operation by the Sturmdorf method. In other words, cauterization was "a between childbirth" form of treatment that was quite efficacious in relieving the leucorrheal discharge and preventing deeper and more extensive chronic infection within the cervical canal and thus preventing the onset of other pelvic symptoms. The Sturmdorf operation, in his opinion, the author said, is the best surgical method we possess for removal of the gland bearing infected cervical mucous membrane but should be reserved for those cases that have deep and extensive infections with cystic changes that cannot be cured with the cautery. Also for those cases of rather marked chronic endocervicitis which must be operated upon for other pelvic lesions and, hence, must take an anesthetic. We do not consider the electric cautery and the Sturmdorf excision operation rival procedures; but believe that they each have very definite indication and that when these indications are fulfilled they offer the most satisfactory means of curing chronic endocervicitis that we, at present, possess.

Low Calcium as a Cause of Intrauterine Mortality.—Dr. Daniel Macomber, of Boston, stated that the importance of calcium in relation to reproduction had long been known. The work of E. V. McCollum, Osborne and Mendel, Hart and Steenboch and their associates had well established this fact. In 1921 Reynolds and Macomber reported the result of a preliminary study of the effect of low calcium upon fertility. None of the previous work, however, had been done with purified substances in the diet on a quantitative basis (with the exception of experiments carried on by Osborne and Mendel) and none had involved a careful study of fertility, pregnancy and lactation in the same animal. For these reasons the present study was undertaken. Ac-

¶ The first advance in the design and construction of bloodpressure apparatus, since the baumanometer was perfected ten years ago, has just been completed.

¶ Sweepingly original — totally different from anything ever done before, the *Lifetime* marks a big step forward. Built upon new, carefully developed principles, it assures perfect, uninterrupted service to the user.

¶ Irritating, costly delays—waiting for factory service—are things of the past, for when the *Lifetime* requires attention (which is seldom, if ever) the user can "service" it himself—quickly, safely, and without the use of any tools.

The announcement

# of a Lifetime

¶ The *Cartridge Tube* can be removed, cleaned and replaced, ready for use again, in a minute's time; and the possibility of its breakage is so remote that we *guarantee* it against that contingency for the owner's lifetime.

¶ Notwithstanding its greater accuracy, smaller size, lighter weight, mechanically perfect reservoir, *Cartridge Tube*, absence of cemented joints and other striking features, the *Lifetime* is the very essence of simplicity.

¶ This development, achieved and sponsored by the only organization in the world devoted *exclusively* to the building of better bloodpressure instruments, will make history anew.

Lifetime
Baumanometer
"STANDARD FOR BLOODPRESSURE"

W. A. BAUM CO., INC. New York

cordingly some sixty-five animals were placed upon a diet containing twenty per cent. casein, four per cent. salt mixture, twenty per cent. lard, and fifty-six per cent. starch. In addition each animal received 0.2 grams yeast, 0.3 grams cod liver oil, and ten grams of lettuce daily. Half of these animals were on a salt mixture which contained no calcium, and half were on a salt mixture which contained five and one half milligrams of calcium to the gram of diet. Each rat ate on the average somewhat less than ten grams of the diet a day. The controls therefore where allowance was made for all calcium in the lettuce, the casein in the drinking water, etc., received on the average about six centigrams of calcium a day and the rats on the diet low in calcium only about six milligrams a day.

The animals were mated during the first stage and if a pregnancy developed were operated upon at about the midpoint and the corpora lutea counted. The number of corpora lutea was subsequently compared with the number of young at birth. In all somewhat more than two hundred pregnancies were observed involving nearly twelve hundred young. The intrauterine mortality for the controls was nineteen per cent.—for the low calcium diet twenty-five per cent., a difference of about thirty per cent., amply large to be significant. The low calcium diet then did materially decrease fertility, but as far as could be determined there was no difference whatever in the weights of the individual young. When the young were analyzed there was, however, a marked difference in the calcium content. Four young from a rat which had been on the control diet during pregnancy contained 0.47 grams of calcium, while four young from a rat on the low calcium diet contained only 0.30 grams. This difference became even more marked during lactation and it was rare indeed that a mother could bring even three or four young to a successful weaning where her diet was low in calcium. Control mothers were able to nurse successfully litters of six to eight. The young themselves from mothers on low calcium were stunted and contained less calcium than those whose mothers were on the control diet. Finally the mothers showed a progressive decalcification as shown by x ray and analyses.

A summary of the results therefore would be that low calcium definitely affects fertility to a slight but statistically significant degree; that it affects pregnancy and lactation by limiting the amount of calcium available for the fetus or nursing young and by causing a definite drain upon the mother. Animals which were not submitted to pregnancy or lactation showed the least drain and those which had undergone pregnancy and lactation the most. The presence of calcium in the diet of the pregnant or nursing human mother becomes then a matter of the greatest importance.

SECTION ON OPHTHALMOLOGY

CHAIRMAN, DR. ARNOLD KNAPP, OF NEW YORK.
SECRETARY, DR. WILLIAM C. FENNOFF, OF DENVER.

Blepharochalasis.—Dr. W. L. Benedict, Chief of Section of Ophthalmology, Mayo Clinic, Rochester, said that blepharochalasis was a disease of the upper eyelids characterized by bagginess and atrophy of the skin. It is usually found in young adults and begins as an intermittent swelling lasting a few hours, the attacks coming on at intervals of a few days to a few weeks. Succeeding attacks last longer and appear more frequently until a permanent swelling of the lids with great thinning of the skin and bagginess of the lids results. The disease is more commonly found in young girls but has been observed in young boys and even in men of fifty or more years.

Little is known regarding the etiology of the disease. The attacks of transient edema appear usually about the time of puberty and the attacks in young girls have been thought to bear some relation to menstruation. In no case, however, has it been reported that the swelling was always coincident with menstruation nor changed to any extent at the period of menstruation.

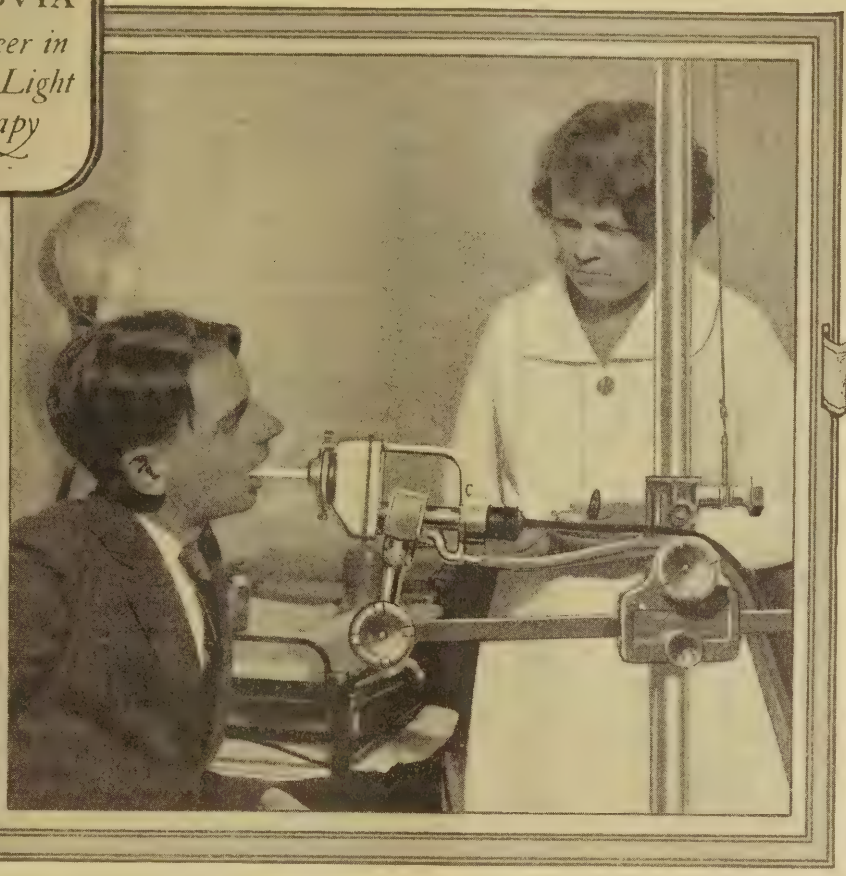
The occurrence of the disease in boys as well as in girls clearly shows that it is not directly related to menstruation, yet the onset at about the same age, that is from ten to seventeen years, places it definitely within the period of functional endocrine development; and perhaps it is a result of that development. That the condition may bear some relation to the development of the thyroid has been suggested by Ascher. In 1919 he described cases in which he noted the occurrence of blepharochalasis with struma and double lip. In 1922, he again called attention to this syndrome and reported two other cases.

In a large surgical clinic in which many cases of goitre were seen, Dr. Benedict said that the syndrome was not noted by him, neither had the syndrome been noted among goitre patients at the Mayo Clinic. He also said that blepharochalasis had not been observed in patients having exophthalmic goitre.

Blepharochalasis is to be found in two stages. The first is the intumescent stage, or stage of edema. The early attacks of swelling resemble those of angioneurotic edema and last usually from two to four days, without pain, and with only slight redness of the skin. after several attacks of swelling one of two things occurs: 1, the swelling becomes constant with bagginess of the skin of the lids so that loose folds hang down over the margin, giving the appearance of water filled bags with the skin slightly altered in color, very thin, and slightly wrinkled or folded; or 2, the swelling disappears entirely or occurs for only short times at intervals of weeks or months, and the skin becomes reddish brown, wrinkled and is thrown into horizontal folds resembling brown wrinkled cigaret paper. The latter condition causes less interference with vision but may be accompanied by true ptosis. This wrinkled and atrophic condition of the skin is the end stage of the disease. It has been confused with chronic atonic ptosis which condition it, indeed, closely resembles, but the latter condition can always be differentiated by the absence of the attacks of swelling.

The only treatment suggested for the relief of blepharochalasis is excision of the redundant skin and subcutaneous tissue, with fixation of the lower margin of the wound to the upper border of the tarsus. If the association of the disease with the development of the endocrine glands can be substantiated, it is probable that some medical treatment can be applied for relief during the intumescent stage. For the

HANOVIA
Pioneer in Quartz Light Therapy



FOR NOSE AND THROAT CONDITIONS

Quartz Light is a potent factor in building up the calcium content of the system. It is also a powerful bactericidal agent. Since coming into use Quartz Light has widely been applied in the treatment of various forms of throat and nose conditions. The acceptance of this therapeutic modality is today world-wide and a number of conservative reports have been favorable to its use in the treatment of Hay Fever and Asthma.

The KROMAYER LAMP is a simple and practical source of Ultraviolet Rays which has been mechanically adapted to conform to the technique necessary for the treatment of such indications. A large selection of suitable quartz applicators devised for such treatment further enhance the value of the KROMAYER LAMP by permitting application to affected parts with the utmost convenience.

We recommend a reading of "The Chemical Action of Ultra Violet Rays" by Ellis & Wells, (Chemical Catalog Co.) price $5. It can be ordered through us.

KROMAYER LAMP

Will be exhibited at the 77th Annual Convention of the American Medical Ass'n. Dallas, Texas, April 19 to 23. Booths 121, 214.

ptosis that results from atrophic changes in the skin, only surgical measures can be applied with hope of success.

SECTION ON LARYNGOLOGY, OTOLOGY, AND RHINOLOGY

CHAIRMAN, DR. SAMUEL IGLAUER, OF CINCINNATI.
SECRETARY, DR. WILLIAM V. MULLIN, OF CLEVELAND.

The Diagnostic Ear Clinic in the Public Schools as a Factor in the Conservation of Hearing.—Dr. Horace Newhart, of Minneapolis, Minnesota, said statistics proved that normal hearing acuity existed in less than fifty per cent. of children of school age. Impairment of hearing at this age signified in many cases the presence of pathological conditions which if not remedied might cause decided hearing loss during subsequent years. Only by regular, careful, periodical examinations of the hearing acuity of all school children could we hope to discover the presence of a slight hearing loss in the many individuals who had it.

Ear examinations as heretofore conducted on a large scale among school children, although legally obligatory in twenty states, had been inadequate for this purpose. Modern methods chiefly through the use of the multiple telephone audiometer made such examinations practically and economically possible. These examinations in our larger cities would be best conducted by a diagnostic ear clinic instituted and controlled by the school authorities. The functions of such a clinic should be carefully defined and limited to diagnostic work. There should be no encroachment upon the field of the private physician or of clinics doing creditable therapeutic work.

The Surgical Treatment of Acute Suppurative Paranasal Sinusitis.—Dr. John J. Shea, of Memphis, Tenn., discussed briefly the surgical treatment of acute suppurative sinusitis, which was of great interest to the physician not doing this type of work. It was really a link between the pediatrist and the rhinologist. The lecture was based on well established principles and practice.

The treatment of acute purulent sinusitis was discussed as emergency treatment and its similarity to acute surgical conditions of the abdomen shown. Incision and rubber tube drainage were given as emergency treatment. The technic of treatment of each sinus was given and the differences and similarities of adult and infant shown. The frequency of childhood infections and consequent failure of sinus growth were discussed and röntgenographic studies shown. Dr. Shea did not consider a sinus cleared of infection until growth could be demonstrated. The technic given for maxillary treatment of these cases was original, the end result being a small rubber tube left in the antrum and nasal vestibule for irrigation or suction.

The prevalence of sphenoid infection and its frequent association with headaches in children were discussed.

Hysterical Dysphagia.—Dr. Herman J. Moersch and Dr. H. Milton Conner, of Rochester, Minn., said hysterical dysphagia was a type of functional dysphagia which is characterized by a sense of obstruction at or about the esophageal introitus, practically always associated with pallor and secondary anemia, and frequently with enlargement of the spleen. The line of demarcation between hysterical dysphagia and other types of functional dysphagia is not always clear or definite, although as a whole hysterical dysphagia represents a very definite clinical entity.

Sixty-five cases were studied, all of which were in women. The average age for the group was forty-five years and the average duration of symptoms eight years. The spleen was palpable in twenty cases, and the average hemoglobin for the entire group was forty-eight per cent. The peculiar pallor in these cases somewhat resembled that of pernicious anemia. Röntgenological examination of the esophagus was negative in fifty cases, but esophagoscopic examination showed that the mucous membrane of the upper part of the esophagus was dry and atrophic with loss of elasticity, and that it bled easily on manipulation.

The treatment consists in passing a plain esophageal sound into the stomach, guided by a previously swallowed silk thread. The size of the sound is immaterial. Usually nothing further is necessary to effect a cure except reassurance. The dysphagia disappears, the blood picture is improved at once, and the spleen may return to normal size. If the trouble recurs, a second passage of the sound will always afford relief.

SECTION ON DISEASES OF CHILDREN

CHAIRMAN, DR. CLIFFORD G. GRULEE, OF CHICAGO.
SECRETARY, DR. HUGH MC CULLOCH, OF ST. LOUIS.

Relationship to Infection in Upper Respiratory Area.—Dr. William J. Mullin, of Cleveland, Ohio, said that experiments on animals had demonstrated routes of absorption from nasal accessory sinuses to the deep cervical chain, peribronchial and mediastinal glands and general circulation. This was substantiated by the clinical evidence. The chronic hyperplastic type of sinus disease was most important in producing secondary infections in the chest. The maxillary sinus was the greatest etiological factor because of its early development and liability to infection, poor ventilation and drainage. Infectious diseases, malnutrition and perhaps heredity paved the way. Secondary chest infections, he said, were acute and chronic bronchitis, bronchiectasis and bronchial asthma.

Hemorrhage From the Intestine Due to Meckel's Diverticulum.—Dr. Isaac Abt and Dr. Alfred A. Strauss, of Chicago, presented the case reports of five infants who were all brought to the hospital with the same complaint, bleeding from the intestine, manifested by the passage of black tarry stools. The infants ranged from nine to twenty months of age, four were males and one a female. In none of the cases were there any symptoms other than the passage of the black stools and progressively developing anemia.

No abnormal findings could be demonstrated on physical examination. Medical treatment of the condition was attempted in the first case but without results. At operation, the cause of the bleeding was found in all the cases to be due to Meckel's diverticula

HORMOTONE
Hormotone presents hormone bearing extracts of the thyroid, pituitary, suprarenal, ovary and testis. Each tablet contains 1-10 gr. desiccated thyroid and 1-20 grain whole pituitary.
Hormotone is a logical combination of these dynamogenic hormones. The usual dose in adrenal insufficiency and asthenic conditions is 1 or 2 tablets before each meal, not more than 6 per day.
In high blood pressure, use Hormotone
Post-Pituitary.

which had undergone inflammatory changes. The diverticulum was successfully resected in all five cases. The authors briefly described the operative technic employed.

A review of the French, German and American literature showed that there had been fourteen cases where Meckel's diverticulum had been accompanied by bleeding from the intestine. In most of these an ulcer was demonstrable in the diverticulum. Many showed heteroplasia of the mucosa with gastric glands present. In almost all perforation with the development of peritonitis preceded the operation.

The authors discussed the symptomatology relative to making the diagnosis preoperatively.

Exophthalmic Goitre in Childhood. — Dr. Henry F. Helmholz, of the Mayo Clinic, Rochester, Minnesota, presented a study of thirty cases of exophthalmic goitre seen in children up to the age of fourteen years; age incidence, signs and symptoms, basal metabolic readings, the use of Lugol's solution in lowering the basal metabolic rate and treatment.

SECTION ON PHARMACOLOGY AND THERAPEUTICS

CHAIRMAN, DR. THOMAS ORDWAY, OF ALBANY, N. Y.
SECRETARY, DR. N. M. KEITH, OF ROCHESTER.

The Action and Clinical Use of Ephedrine, an Alkaloid Isolated from the Chinese Drug, Ma Huang.—Dr. K. K. Chen, of Madison, Wis., and Dr. Carl F. Schmidt, Philadelphia, said that the crude drug ma huang *ephedra vulgaris, var. helvetics,* has been in medical use in China for more than 5,000 years. No scientific study was made until Yamanashi (1885), Nagai (1887), and Merck (1888) isolated an alkaloid named ephedrine. Brief pharmacological investigation was undertaken by Takahashi and Miura, and later by Amatsu and Kubota. In 1923 Chen reisolated ephedrine from the stems by a different method. The alkaloid has been submitted to extensive experimentation by the authors. He said it acts like epinephrine, only its effects are much more prolonged. When taken by mouth, in doses of 100 to 150 mgm., it raises blood pressure for several hours, and relieves certain types of asthma. Ephedrine shrinks congested nasal mucosa for an average of two to three hours without subsequent vasodilatation. The drug is stable and has a low toxicity. Favorable clinical results have been reported by many investigators.

Thyroid Therapy and Thyroid Tolerance in Chronic Nephrosis.—Albert A. Epstein, of New York, said the term "nephrosis" had been applied to a group of nephropathies which presented certain definite clinical manifestations with characteristic blood and urinary findings. Among these there were certain cases which showed no evidence of inflammatory renal involvement, but in which all the manifestations pointed to a primary metabolic disorder. To this subdivision he had applied the term "diabetes albuminuricus."

The object in the treatment of this disease was threefold: 1, To replace as much as possible the protein lost from the blood; 2, to compel the tissues to utilize the lipoid accumulation in the blood; and 3, to reestablish normal metabolism. These requirements were best fulfilled by feeding the patients the high protein, fat poor diet which he had introduced some years ago. In certain cases the high protein diet accomplished all that was required of it; in certain other cases it stopped short of a complete cure. In these cases the addition of thyroid therapy would accomplish this result. There were still other cases in which the protein therapy would not produce any effect until thyroid was administered. It was often necessary, however, to give the thyroid in increasing doses until a definite effect was produced. In certain instances the tolerance for thyroid extract was quite remarkable and very large doses were required.

SECTION ON PATHOLOGY AND PHYSIOLOGY

CHAIRMAN, DR. HARRY J. COWPER, OF DENVER.
SECRETARY, DR. JOSIAH J. MOORE, OF CHICAGO.

Avitaminosis, With Symptoms and Lesions of Beriberi Predominating, Occurring in the Course of Diabetes.—Dr. Michael G. Wohl, of Omaha, Neb., said that among the many diseases classified as avitaminosis, beriberi and keratomalacia have received considerable attention. Human and animal feeding experiments have proved that both of these diseases essentially follow deprivation of water soluble vitamine B and fat soluble vitamine A, respectively. In this country patients presenting symptoms of beriberi or of keratomalacia are rather uncommon. This was rather surprising, he said, considering the great number of patients who were on restricted diets. He felt that there must be a greater number of cases which may show individual symptoms of these diseases, but pass unrecognized as such.

The author has studied both the clinical and post mortem findings of a patient who came under his observation, who developed during the course of a restricted diabetic diet cardiac neurotoxic symptoms of beriberi and the eye symptoms analogous to keratomalacia. From a study of the literature and of this case, a few points suggested themselves, deductions from which were sufficiently cogent to merit mention, such as: 1, extreme muscle weakness, which occurred during the course of diabetes, and which could hardly be explained by the loss of calories. Food deficient in vitamines which caused atrophy of the glands of internal secretions. The deficiency need not necessarily be complete. The symptom of asthenia during diabetes could be accounted for on the basis of histological changes induced by avitaminosis in the endocrine glands; 2, neuralgic pains might possibly be explained as due to the disordered metabolism of nerve cells with more extensive degeneration incident to avitaminosis when continued for too long a time. Twenty-two patients out of eighty diabetics studied, showed symptoms of paraesthesia, partial loss of knee jerks and neuralgic pains particularly in calves. A careful inquiry into the dietary habits revealed that sixteen of them consumed food poor in vitamines, such as potatoes, bread, meat, etc.; 3, constipation was a common symptom diabetics complained of. It has been found that vitamine B deficiency produced intestinal stasis, atrophy of abdominal muscle and disordered function or actual degeneration of nervous tissue. The most remarkable point

VEGEX
THE VITAMINE YEAST EXTRACT

Diabetes and Constipation

Due In Part To Vitamin B Deficiency

VEGEX, The Physician's Ready Aid

The American food bulk is vitamin deficient; particularly in the B vitamins. That constipation, diabetes, and a train of other disorders are due in the main to this deficiency is now confirmed by an amount of clinical evidence, from workers in America and Europe of such ability, as can be no longer questioned.

The facts are now up to the physician.

Gastro-Intestinal Disorders

McCarrison in "Deficiency Diseases," as the result of wide studies in London, Asia and India, pointed out:

"The health of the gastro-intestinal tract is dependent on an adequate provision of accessory food factors; especially Vitamins B and C. The absence of Vitamin B is capable of producing pathological changes in the tract which frequently assume the clinical form of colitis. This observation is of the highest importance in view of the frequency of this malady."

Disorders of the Pancreas

Mendel, McCarrison, Lopez-Lomba, Klotz and Hopfner have found that a diet deficient in Vitamin B affects the health and a normal functioning of the pancreas. Yeast extract, rich in Vitamin B, has been successfully used by Klotz and Hopfner in Germany, and by Levine and others in the United States as a diet aid in reducing the sugar content in diabetes.

Constipation and Intestinal Stasis

Dr. R. H. A. Plimmer of St. Thomas' Hospital, University of London, has completed and reported a two-years' study of the amount of B vitamin needed in the diet. The *British Medical Journal,* in reviewing the work states:

The experiments showed very clearly that one of the chief effects of a partial deficiency of vitamin B was to produce intestinal stasis which resulted in the retention in the bowel of putrid food residues and the absorption of products of putrefaction. McCarrison had noted this intestinal effect.

Professor Plimmer suggested that the fundamental effect of vitamin B lack was to produce atony of the gut, and that polyneuritis was possibly due to absorption of some toxic products of putrefaction. He pointed out that these experiments raised the very serious question as to whether the supply of vitamin B in normal human diets was really adequate.

Dr. Louis Gross, of Montreal, working with the British Medical Association of London, studied the activity of the alimentary canal in vitamin deficiency, and adequate vitamin feeding. He used the VEGEX yeast extract as the source of his vitamin B, and found that the administration of small quantities of VEGEX extract restored the normal number of scybala per day.

Diabetes in Part a Vitamin B Deficiency Disease

The report of Dr. Michael G. Wohl of Omaha at the Dallas Convention of the A. M. A. confirms these findings with clinical data which can be no longer questioned. Dr. Wohl finds that atrophy of the glands of internal secretion, asthemia during diabetes, disordered metabolism of nerve cells, intestinal stasis, atrophy of abdominal muscle, the disordered functional capacity of the pancreas and constipation in diabetes are due, in a large part, to vitamin deficiency and particularly to vitamin B deficiency. Dr. Wohl cites the work of Gross and the report states:

"The most remarkable point in experimental work by Gross was that the intestines seemed to feel the need of vitamin B almost immediately."

VEGEX Makes Up Deficiency in Vitamin B

In all of the work, yeast extract or the vitamin from yeast has been used as a source of the B vitamin. In most of the work the VEGEX yeast extract has been selected as the richest and most dependable source of the vitamin. It is free from fermentation and spoilage, does not contain carbohydrates and sugar, and is very palatable.

The Vitamin-Deficient Food Bulk

The evidence, to quote the *British Medical Journal,* "shatters the comfortable belief that we have enough vitamins in the diet." The American food bulk is vitamin-deficient. Refined sugar, vegetable fats and oils, white flour and meat products make up a total of 2300 calories per individual per day. The evidence now shows the wide train of disorders which have followed the vitamin deficiency. It is not made up by vegetables. There are not enough produced, not enough consumed. Milk consumption is less than one-third of the requirement per capita and milk is deficient in the B vitamin and in other factors necessary for adolescent growth and adult health.

Butter and cod liver oil make up the vitamin A deficiency. It doesn't take much of orange juice or green vegetables to make up the vitamin C deficiency. VEGEX in food form and at a food price economically makes up all deficiency in vitamin B.

in experimental work by Gross was that the intestine seemed to feel the need of vitamine B almost immediately. The idea that constipation in diabetics was possibly dependent upon improper food rather than the diabetic condition as such was not inconsistent with the above facts. Eight diabetics with obstinate constipation received each 800 milligrams per day of Osborne and Wakeman fraction of yeast vitamine B. Six gained normal bowel movement and two have improved. Increase in the incidence of diabetes in this country may be attributed to the changed conditions, especially with respect to food habits, consumption of luxurious but vitamine deficient food. The author said the lack of vitamine in the food had a depressing effect upon the functional capacity of the pancreas. A case was reported with postmortem findings.

The author's conclusions were, 1, the purpose of this paper was to emphasize the rôle which avitaminosis possibly played in the production of symptoms in cases of diabetes mellitus; 2, insufficient training of both parent and patient in the care of diabetes were possibly responsible for such avitamosis and led to disaster for the patient; 3, the clinical and pathological findings of a diabetic patient who developed a condition like beriberi and eye lesions somewhat analagous to keratomalacia, as a result of improper diet, were described in detail.

SECTION ON NERVOUS AND MENTAL DISEASES

CHAIRMAN, DR. JAMES B. AYER, OF BOSTON.
SECRETARY, DR. JAMES J. POLLOCK, OF CHICAGO.

Glioma of the Pons Varolii Simulating a Frontomotor Growth.—Dr. Tom B. Throckmorton, of Des Moines, Iowa, stated that a hemorrhagic glioma of the left half of the pons produced a symptom group in which the cardinal symptoms of increased intracranial pressure—headache, vomiting, and choked disc—were practically absent, while localizing symptoms pointed more to the possibility of a subcortical growth in the left frontomotor region as evidenced by an unstable emotional state in which forgetfulness and alternating phases of mild exaltation and depression with crying episodes played an important rôle, associated also with a rightsided hemiplegia.

Aneurysms of the Cerebral Vessel; Their Clinical Manifestations and Pathology.—Dr. Harry L. Parker, of Rochester, Minnesota, said that the diagnosis of cerebral aneurysms is somewhat difficult, and they are more frequently found accidentally at necropsy. The factors responsible for their production are mainly arteriosclerosis, congenital weakness of the vessel wall, septic emboli and lues. Lues plays a relatively smaller part in the production of cerebral aneurysms than it does in the vessels elsewhere in the body. The location of cerebral aneurysms is more frequently at or in the neighborhood of the circle of Willis. The course of the disease and symptoms vary according to the underlying cause of the aneurysmal dilatation, the site of the aneurysm and the integrity of the aneurysmal wall. Aneurysms produced from septic emboli produce signs that are likely to be masked by the underlying illness usually acute or chronic vegetative endocarditis. Aneurysms arising from the anterior portion of the circle of Willis produce signs of involvement of the third, fourth, fifth and sixth cranial nerves in the optic tracts. Aneurysms arising from the posterior portion of the circle of Willis tend to compress the pons and medulla and produce corresponding symptoms. Rupture of an aneurysm may produce sudden death with all the signs of hemorrhage at the base of the brain. Commonly there is intermittent leakage of the aneurysm with multiple apoplectiform attacks. There may be little or no signs of illness in between these attacks. More usually there is certain amount of residual symptoms. Four case records illustrating these points were given with the discussion of each case.

Sympathectomy in Angina Pectoris.—Dr. E. C. Cutler, and Dr. J. Fine, of Cleveland, presented a study of sympathectomy in angina pectoris with a lantern demonstration. They stated that angina pectoris was a symptom complex. There were no constant pathological findings; therefore, the condition had been called by some a neurosis. This would not satisfy those who actually studied and treated the condition. Theoretical considerations would seem to justify surgical interruption of the nervous pathway to give symptomatic relief. They then discussed the innervation of the heart. All cardiac sympathetic afferent nerves passed through the stellate ganglia. An overflow of impulses via the vagus could not give the location of pain seen in angina pectoris. A discussion followed of the various forms of operative procedure which had been proposed. Inability to obtain complete relief was common when the operative procedure used did not attack the stellate ganglia. Seven cases were cited, some of which had been observed two to three years after several different forms of operative therapy. The grave risks involved were emphasized, and the difficulty of selecting proper cases. The procedure was still in the experimental phase, they said. Unfortunately animal investigation was of no further assistance. They made an earnest plea that only those patients be operated upon which could be carefully studied before hand and followed for years until the end result was determined. Much indiscriminating operating was now being done. The authors concluded that if any operation was to be done it should include removal of the stellate ganglion, i. e., Jonnesco cervicothoracic sympathectomy.

Some Infantile Etiological Factors of Hysteria.—Dr. M. S. Gregory, of Oklahoma City, said that in addition to the classical definitions of hysteria, he wished to maintain that hysteria was the reaction of the infant; that the specific symptoms were largely repetitions of action patterns established during early life. In consideration of hysteria heredity must be discussed. With many psychiatrists the concept of heredity had changed. No one repudiated heredity but rather believed that mental mechanisms were built upon an inherited basis as reactions to environment, frequently appearing quite independently of heredity.

The babe brought with him by inheritance the intincts of the animal kingdom. He was received by

The *solid* handle permits complete sterilization

BARD-PARKER handles are made in one solid piece retaining the shape and balance of the one-piece scalpel. There are no springs, catches or hidden crevices to prevent complete sterilization.

The blade slides onto the handle and forms a mechanical lock when in position. No amount of pressure in any direction will remove the blade during an operation.

A new Bard-Parker blade, slipped onto the handle, provides you with a keen razor edge for only 12½ cents—just *half the cost* of resharpening an ordinary scalpel.

One No. 3 handle and one-half dozen each of Nos. 10, 11 and 12 blades—$3.25

BARD-PARKER COMPANY, INC.

150 Lafayette Street, New York, N.Y.

one of two types of mothers. One spoiled her babe by excessive care and loving while the other was sensible in its care. The child of the first mother had great difficulty during the weaning and other training. This child had great trouble in adult life, for as an infant is trained and conditioned to receive love and attention during its first year of life, so it will demand love and attention as an adult. During the second and third years of life the mother frequently became ugly and cross and the child was compelled to repress much of its love, and when infantile love is repressed, fear, dread and depression are frequently put into its place.

During the first five years of life the child frequently develops abnormal means of winning its wishes, as by falling upon the floor, kicking and screaming, holding its breath or throwing a fit. When a child wins by abnormal conduct, it will strive as an adult to win by the same type of conduct. Frequently the child is trained by the loving mother to love medicine, and such always enjoys poor health.

In normal families certain relations exist: for example, the boy *loves* and worships mother while he *identifies* himself with his father, i. e., he loves mother but wants to be like father. This mechanism is normal up to a certain degree, but when the boy overloves mother and mother overloves the boy then a serious mental condition exists, for if he is too tightly tied to her he cannot free himself from her, and becomes an infant in his adulthood. He not only may become a hysteric but may become a precox as well. Similarly, the girl may be too tightly tied to her father. She may marry, but failing to receive from her mate the petting of her childhood she may flee from reality by running home to her father, or going to bed and being ill.

An Unusual Case of Subacute Combined Cord Degeneration.—Dr. Walter F. Schaller, of San Francisco, reported the following case: Male, aged fifty-eight, ambulatory, in apparent good general physical and mental health, presented a spastic paraplegia of gradual onset (seven years) and a history of recent unsteadiness on walking. There was clinical evidence of pyramidal tract involvement, but the tests for incoordination and ataxia were inconclusive. No sensory loss, no anemia, leucocytosis, neurosyphilis or inflammatory cerebrospinal fluid was present. A clinical diagnosis was made of spastic paraplegia of undetermined origin. Following a prostatectomy the patient died of pulmonary embolism. A complete necropsy was done. The nervous system showed marked atrophy of the cerebral cortex with the exception of the temporal and occipital lobes, and marked sclerosis of the lateral and posterior columns of the spinal cord. A discussion of the histological picture was presented.

Social and Economic Aspects of Nervous and Mental Disease.—Dr. Theodore Diller, of Pittsburgh, Pa., said that as every one knows nonscientific aspects of disease are of vast importance; yet they are seldom or never discussed at meetings of medical men. The most important of these nonscientific aspects, he said, are the humane, social and economic, and, while they are problems belonging to all classes of disease perhaps most important of all is their relationship to nervous and mental disease. The old fashioned physician who was kindly and humane, often lacked sadly in technical skill; whereas the highly technical physician today, especially among the younger men, often lacks sadly in the human touch. There need be no antagonism between the highly developed technical skill and the human side of the physician's makeup. The scientific and the humane should be combined. They were combined in the great leaders in neurology and psychiatry in a way worthy of emulation. They were combined in a peculiarly intimate way in William Osler, the study of whose life should be required of all medical students. The physician should not only cultivate and develop the humane side himself but he should use his influence to counteract the tendency often seen in nurses and social workers to become too technical and too mechanical. Some of the younger physicians today examine the patient as though he were a mechanical instrument or chemical retort. This is a mechanical world and we are becoming increasingly more urban, and sick people are more and more being cared for in hospitals. There is great danger in organization in that the sacredness of the human personality will be jeopardized. The human qualities of the physician were never more needed than they are today.

The trained nurse, and now the social worker, are of enormous value to the physician, especially if he practises in the city hospital, and used rightly they bring to him social and economic aspects of the patient which otherwise would be impossible. But the physician himself should cultivate the habit of becoming acquainted with members of the patient's family from whom he often derives most helpful information, and from consideration of whom he may better appreciate the sort of man or woman he is dealing with. Personality is sacred. This is close to the religious side—indeed, it is the religious side. The physician recognizes the comfort and support from religion which comes to many men and women and he must account it as a thing to be reckoned with. The value of the earnest, sincere, wise chaplain in the army, navy and sanitorium is widely attested by our best medical men. The physician shows his good heart by the way in which he makes a prognosis. The truth ought to be told; but it may be told in a way that hurts when this is not necessary. The physician should seek to express the truth in a way that hurts the least.

Sickness is expensive business. The necessary part of it is expensive. Hospital charges, consultant's, nurses' and attending physician's fees added together often make a staggering total. Unfortunately much of this cannot be avoided, but some of it can. There are today many unnecessary examinations, consultations, etc. It is plainly the physician's duty to conserve the patient's finances. Often it is difficult or impossible; but he should make what effort he can. The patient should be warned against undertaking hospital expenses which are likely to continue for many months. Here the physician's duty is to think of the welfare of the patient's wife and family as regards financial outlay.

The author states that the whole point of his brief paper was this: Let the physician acquire and employ for the benefit of the patient all possible technical skill; but let him never forget that his patient is a

Let's Reason Together

By C. H. WOODWARD

It is *too late* to call the doctor *after* function of the life-processes has ceased, accordingly, the doctor is *always* called *only* to *restore altered function,* never *ceased* function.

Whatever the *specific condition* may be named—however it may be described—it is *always* a manifestation of *altered* function.

Since the doctor is *always* called *only* to restore altered function to normal function, he *must* of *necessity* be interested in the *fundamentals* on which *function* rests.

Function, or operation of the life-processes, is dependent upon just five things. They are:

Natural air,
Natural water,
Natural sleep,
Natural exercise,
Natural food.

If the doctor, called to treat a patient for *any* condition of *altered function,* ignores or neglects to control these five fundamentals, can he *reasonably expect* to restore his patient to *normal* function?

His first step in restoration is to *control all* these fundamentals.

Ask yourself this *serious question:* What are you doing in controlling the *food* intake of your patients?

Man's food today is practically universally denatured or made unnatural. It is made unnatural through having its nature changed by separation into parts and the rejection of some part, or by cooking in the presence of the oxygen of the air, thereby oxidizing its minerals, evaporating its volatile elements, distilling out its minerals and precipitating them on the walls of the cooking vessel, and changing or destroying its vitamine-effects.

If you boiled your gasoline would it operate your automobile engine normally?

Natural food—food from the vegetable kingdom as grown under natural conditions, the seeds, the leaves, and the fruits—is *just as important and fundamental to life* and its *normal* function as natural air, or natural water, or natural exercise, or natural sleep, but it is almost universally ignored *while* the patient is *under* the doctor's *care as well as before and after.*

Whole Grain Wheat and other natural Thumb-Print Products, (***Whole Grain Rice, Whole Ripe Peas, Whole Lentils, Whole Lima Beans, Whole Red Kidney Beans, and Liquid Life***) *are natural foods* because they are the natural substances and are identical in their biological or nutritional effects with ripe, raw substances and are the *first* such substances *cooked ready-to-eat of which that statement can be made.*

Add ***Whole Grain Wheat*** or any of the natural Thumb-Print Products to the food intake of your patients, not as a "cure" or a remedy, but merely as a *natural* food, and watch how your patient responds—*any condition where food is or may be taken.*

Whole Grain Wheat and other natural Thumb-Print Products are never sold through grocery stores, but only by authorized distributors, and come in packages of one dozen 11-oz. tins $2.00 or 4 doz. $7.60 Denver and east; $2.25 per dozen or 4 doz. $8.30 west of Denver. Look in your telephone directory for Whole Grain Wheat Distributor, or send direct to Whole Grain Wheat Co., 1832 Sunnyside Ave., Chicago; Chicago readers telephone Ravenswood 4101; Canadian address 26 Wellington St. E., Toronto; Toronto readers telephone orders Main 4489; New York readers telephone orders Bowling Green 3250.

Watch for Next Month's Reason

sick man, a sick brother, a fellow human being, and that he must treat him with all possible kindness and consideration. Moreover, it is the physician's duty by precept and example to encourage such consideration on the part of nurses, and must resist any tendency he may observe in them to make their work mechanical or routine. It is his duty to put forth his best efforts to help the patient from a social and economic point of view as well as a scientific; and he may not do his full duty by neglecting these considerations.

Physiology of the Sympathetic Nervous System in Relation to Certain Surgical Problems.—A. Forbes and S. Cobb, of Boston, stated that on the basis of a theory that a special function, designated "plastic tonus," in skeletal muscle depends on sympathetic nerve fibres, believed to innervate some of the muscle fibres, the operation of ramisection had been advocated for the relief of spastic paralysis. Testing the physiological basis of the theory had been tried by measuring decerebrate rigidity with spring balances in cats decerebrated at varying intervals after removal of the sympathetic innervation of the fore leg or hind leg on one side. The difference between the operated and unoperated sides was usually so slight compared with chance fluctuations of rigidity that no significant change can be ascribed to the operation. This fact, they said, together with the failure of the conception of a special plastic function to harmonize with the known properties of nerve and muscle, rendered unsound the physiological basis for this surgical procedure.

The Connotation of Constitutional Psychopathic Inferiority Without Psychosis—A Study of Five Hundred Diagnoses.—Dr. James H. Huddleson, of New York, said that twenty-one attributes, separately or in various combinations, were found to have conditioned the diagnosis in these cases. The most frequent were forms of emotional instability, seen in sixty-three and one half per cent. of case histories bearing this diagnosis. These and other psychopathic characteristics were necessarily shown to be fundamental traits, not acquired in later life, to justify the diagnosis. The latter was best understandable as a symptomatic, not a pathological, expression, the pathological basis for all such symptoms being too much in dispute. While the term criminalism may be occasionally employed to define a symptomatic group under the head of psychopathic inferiority, it so readily lends itself to construction as a pathological or quasipathological conception—not yet justified by generally accepted data—that it would better be omitted from a nomenclature of diseases.

SECTION ON DERMATOLOGY AND SYPHILOLOGY

CHAIRMAN, DR. FRED WISE, OF NEW YORK.
SECRETARY, DR. JAMES H. MITCHELL, OF CHICAGO.

Bullous Ichthyosiform Erythroderma: Report of Two Cases.—Dr. William H. Goeckerman, of the Mayo Clinic, Rochester, Minnesota, reported two cases of bullous ichthyosiform erythroderma. The observation of these cases permitted of some plausible deductions relative to the developmental mechanism responsible for the production of bullæ in an ichthyotic skin. The first case especially seemed well adapted to demonstrate the possibility that these bullæ might be essentially, at least in some cases, the result of an abnormal sweat retention. The second case was especially striking because the eruption of bullæ was much retarded by x ray treatments.

The author's observation of these cases as to their clinical behavior, seemingly so similar and yet different in many respects, suggested to him that we were dealing with this entire group of socalled ichthyosiform erythroderma with varying degrees of developmental disturbance throughout the entire skin of such individuals, whether this could always be demonstrated histologically or not. This, he said, in combination with a careful review of the literature made him feel that all the various forms of ichthyosis and many other dyskeratosis were not different entities, but genetically the same disturbance. The difference, for instance, between a simple asteatosis and an ichthyosis congenita was one of degree only.

Critical Investigation of the Relation of the Endproducts of Protein Metabolism to Eczema and Kindred Disorders.—Dr. Jeffrey C. Michael, of Houston, Texas, said that the present investigation was undertaken to determine the value of the hypothesis that hyperuricemia was associated with, and probably was an etiological factor in many cases of eczema and pruritus cutaneous. This old hypothesis has received considerable support recently by the findings of Schamberg and Brown and others. The study was carried out in four ways: 1, blood chemical estimations; 2, intracutaneous injections; 3, intracutaneous injections plus comparative photodynamic tests and 4, intravenous injections of urate solutions. Most stress was laid on the uric acid. Urea and creatinin were added to complete the triad of protein endproducts. In all, approximately 120 persons have been tested, only two intravenous injections experiments have been performed, about half of whom were sufferers from eczema or pruritus cutaneous.

The results were essentially negative, and the conclusion reached that uric acid, urea, and creatinin play little, if any role, in the causation of these disorders.

Sporotrichosis, an Occupational Dermatosis.—Dr. Harry R. Foerster, of Milwaukee, Wis., said that sporotrichosis, an infectious granulomatous disease of worldwide distribution, has shown an endemic occurrence in certain parts of the temperate zone, particularly in the Mississippi river basin. He stated that it is a disease peculiar to outdoor workers most of the cases reported in the United States having occurred among farmers, horticulturists, and the like. Of 148 American cases reviewed, 111 showed primary involvement of the distal portion of an upper extremity, and most of the infections caused disability for work. Fourteen cases have been reported among employees of a Wisconsin tree nursery, of whom ten definitely acquired the infection from the barberry shrub. The latter shrub, having a distribution in nature similar to that of the sporothrix, is considered of importance as a host of the organism and as a possible disseminator of the disease. The occupational hazards and disabilities peculiar to sporotrichosis entitle it to consideration among occupational dermatoses.

KISSINGEN (Bavaria)

roubles of the HEART, DIGESTIVE ORGANS, ARTERIO-SCLEROSIS, GOUT—Carbonic Acid, and Mud Baths. All Kinds of Sports—Especially Golf Season: March-November
gen Mineral Waters imported by SPA PRODUCTS, Inc. 105 Hudson Street, New York, N. Y.

BAD EILSEN (near Bueckeburg)

utiful Spa in the romantic Weser Mountains. Famed for its sulphur water massage treatment of AND RHEUMATISM. Modern Mud Baths applied in an especially sanitary way.

FIFTH AVENUE, NEW YORK

SECTION ON PREVENTIVE AND INDUSTRIAL MEDICINE AND PUBLIC HEALTH

CHAIRMAN, DR. MATTHIAS NICOLL, JR., OF ALBANY.
SECRETARY, DR. W. F. DRAPER, OF WASHINGTON, D. C.

The Sanitary Officer and County Health Work.—Dr. E. L. Bishop, of Nashville, Tenn., said he believed public health work to be essentially a thing of personal service, even though dealing principally with its problems upon a community basis; hence, to be most effective must be administered with the political unit of government as the unit of health organization. He discussed the "standard minimum" for whole time county health departments, which he said was possible for only a part of the population in certain states. Other solutions of the problem might begin with one or more elements of the full department. He discussed the possibilities and limitations of the sanitary officer and the possibilities of growth and expansion of a service thus begun. His summary and conclusions were of great practical value.

Protective Health Measures on the United States-Mexico Border.—Dr. J. W. Tappan, of El Paso, Tex., said that the difficulties in safeguarding the health of our southern border seem, at first sight, insurmountable. Extending as it does from the Pacific Ocean to the Gulf of Mexico, the border is sparsely settled for long distances and legalized ports of entry are far apart. There are sixteen such ports scattered along 3698 miles of border. Five of these have direct connection by rail with the interior of Mexico, while the others have more or less indirect communication with the interior, depending upon their nearness to, or remoteness from, railroads or other routes of travel. The national quarantine is concerned with the quarantinable diseases—cholera, yellow fever, plague, smallpox, typhus fever, leprosy and anthrax. The medical inspection of aliens, carried out by authority of the Immigration law, covers communicable and other diseases in the case of immigrants.

If certain communicable diseases are present on the border, even if such diseases are imported from Mexico, they should be dealt with as local problems. Local health authorities must be prepared for such contingencies and the best solution of border problems lies in complete cooperation between federal, state, county and municipal health authorities. Under such circumstances communicable diseases which, in spite of vigilance, may get into the United States, can hardly spread to a dangerous degree.

Relation of the Medical Practitioner to the Public Health Program.—Dr. G. S. Luckett, of Santa Fe, N. M., said that this subject is trite but needs constant reiteration. He cited examples from current experience and attitude of the American Medical Association, of the medical opposition or indifference to the modern health program which was not by any means universal, but important in effect upon progress and upon the public attitude toward medicine. He said that the causes of this opposition or indifference were: 1, lack of information and understanding on the part of the profession; 2, faults of the health program and of the workers themselves; 3, mercenary consideration of a few physicians; and that the effects of this opposition are: 1, to delay development of a modern program in some parts of the country; 2, to arouse public resentment toward the profession and suspicion of its motives. The speaker suggested that this may react to encourage cults, and that the public is fairly "sold" to a preventive program. Among the solutions he suggested were: 1, modernization of courses in preventive medicine and hygiene in medical schools; 2, greater wisdom in public health policies—sound judgment in planning and executing, spirit of cooperation with profession, better presentation to profession of plans and results; 3, recognition by profession of preventive medicine as part of its field, e. g., periodic health examinations; 4, leadership on part of profession in development of an all comprehensive program of preventive and curative medicine for all of the people, before initiative is seized by non-medical groups and forced on physicians. The author further stated that health workers are neither responsible for the latter trend, nor desirous of it, but are powerless to stem the tide alone.

SECTION ON UROLOGY

CHAIRMAN, DR. B. A. THOMAS, OF PHILADELPHIA
SECRETARY, DR. GEORGE GILBERT SMITH, OF BOSTON.

Cystometric Determination of Bladder Pressure.—Dr. D. K. Rose, of St. Louis, said the instrument called a cystometer recorded the amount of fluid flowing into a bladder either through a cystoscope or a catheter from the first c. c. to full capacity and simultaneously recorded in mm. of mercury the changing pressure within the bladder. Based upon a study of innervation of the bladder, curves were plotted between c. c. of fluid and mm. of mercury, which indicated the type of lesion of the spinal cord. Furthermore, the condition of the bladder wall itself was shown to be either hypertonic or atonic. The threshold of sensation was also recorded indicating the state of irritability together with the bladder wall tone. It was possible by means of the cystometer to supplement cystoscopic data in all types of urological cases. The paper was accompanied by a presentation of the instrument and a lantern demonstration.

Prognosis with Chronic Pyelonephritis.—Dr. W. F. Braasch and Dr. E. P. Cathcart, of the Mayo Clinic, Rochester, Minnesota, presented a review of three hundred cases of chronic pyelonephritis treated ten years or more ago and five hundred cases treated from five to ten years ago. They compared the various methods of treatment, described the cases requiring surgical treatment, the course of the disease when not treated, the significance of hematuria with pyelonephritis, and the type of pathology causing unfavorable prognosis.

Stricture of the Female Urethra.—Dr. Winfield Scott Pugh, of New York, said that the archives of medicine held scant but rather interesting comments on stricture of the female urethra. It was mentioned at least as a possibility by Fabricus in the early days of the anatomical school of Padua; the first real description was that of Lisfranc in 1824. It was apparently and routinely taught and generally accepted that stricture of the female urethra was rather a rare entity. This was never convincing, and when the author first began his original

In All Conditions Where

studies over 3,000 gynecological and urological records were examined in this country and abroad. It was found that only four cases were definitely diagnosed as urethral stricture of the female. These were all cases that were readily diagnosed, one a carcinoma, one obstetric tear into the urethra and three cases of marked gonorrheal infiltrations. Other extensive reviews have been made, with practically no further results. In discussing the cause of this condition, many medical writers seem to have ventured quite far afield, while the real factor was among the best known offenders. It was believed that trauma was important, birth injuries, catheter injuries and other accidents. Neoplastic pathology was drawn on extensively. Two new growths were particularly mentioned, caruncle and papilloma, and in the late eighties members of the London Obstetrical Society were impressed by the relatively frequent occurrence of lupus and lupetic ulceration in these cases.

Syphilis was also mentioned as a possible cause. The author stated that practically all of the socalled etiological elements sink into oblivion when compared with the gonococcus. Embryological conditions may produce factors, which to say the least, predisposed to urethral obstruction, but one cannot escape from the impression that the doubtful cases were Neisserian infections. The author now discussed the pathology and symptoms of the infection, and said that stricture of the urethra in women was common, and that the principal cause was a gonococcus infection. The pathology was quite similar to that of the urethral stricture in the male. Its most common location was at the external meatus, and the most common symptoms were frequency, urgency and dysuria. He said the diagnosis may always be established by olivary tip or bulbous bougie; the prognosis was good in soft infiltrations, while that of dense strictures was doubtful. Treatment was by gentle dilatation, operative procedures to be avoided, if possible, as the female urethra was a delicate and very sensitive organ. Rapid dilatation should not be attempted in order to avoid severe hemorrhage. Gradual dilatation was always best, and should begin with the largest sound or bougie that will pass the stricture.

Bilateral Pyeloureterograms.—Dr. Abraham Mattes, of New Orleans, La., said that due to the fact that fatalities have been reported following the injection of fluid into kidney pelvis, and that harmful reactions have resulted from its employment in other cases, a number of urologists discontinued the taking of bilateral pyelograms. It was due to the work of those who still feel that there was danger attending the injection of the pelvis, that unilateral pyelograms were still in vogue. In fully twenty-five per cent. of the cases, unless a bilateral pyelogram was taken, or a picture of the opposite side taken later, the diagnosis will be faulty or incomplete. Bilateral pyelograms should be employed in each and every case.

The author said that the pelvis was a flat sac, its capacity always less than three c.c. and usually one to two c.c. It should be visualized as a flat sac in our pyelograms. Since the injection of one to two c.c. above its capacity did not enlarge the shadow, but only increased its density, the use of larger amounts was unnecessary. Larger amounts than three to four c.c. dilated the pelvis and gave an untrue picture, increased the tendency to discomfort and other symptoms. The emptying time of the pelvis was from three to five minutes, therefore pyelograms should be made always bearing in mind the physiological activity of the pelvis and ureter. A method that would cast a shadow of the functioning pelvis and ureter in as short a period of time as possible, and that did not interfere with its function, was the physiological one and should be employed. Briefly it was as follows:

Essentials: 1, the lack of preparation of the patient; the use of small opaque ureteral catheters; 3, the instillation of small amounts of fluid; and 4, the use of higher percentage solutions, as forty per cent. sodium iodide.

Method: Four or more pictures were usually taken. The first showed the course of the catheters. The second plate followed the injection of each pelvis with from three to four c.c. of fluid. The third picture was taken following the simultaneous injection and complete withdrawal of the catheters, one to three c.c. solution was used to each side. The fourth picture was taken in five minutes, and later others if indicated.

Summary: In over 1200 cystoscopies since January 1924, bilateral pyelograms were made in over 229 cases with no attending fatality, or any real serious complications when small amounts of fluid were used. In forty cases forty per cent. sodium iodide was used with no increase in symptoms usually noted. The flat sac method of instillation was physiological and did not distend the pelvis, nor interfere with its function. The capacity of the pelvis was one to two and a half cubic centimetres, rarely three cubic centimetres. The emptying time of the pelvis was three to five minutes.

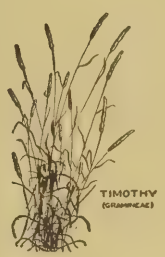
The author said that time pictures gave valuable information that would otherwise be lost. In conclusion, he remarked that 1, bilateral pyelograms properly made were safe and were attended with no danger to the patient; 2, the pelvic sac should not be distended; 3, the physiological function of the pelvis and ureter should not be disturbed in any examination, or the interpretation of findings would be false; 4, a mild degree of stasis could always be determined by time pictures; 5, the taking of time pictures may eliminate the use of bougies for the determination of the presence of stricture or spasm in the ureter; 6, pain referable to the kidney area frequently showed, on examination, no more than retension of pyelographic media; and 7, socalled pelvic stasis responded to drainage and dilatation, with cessation of symptoms.

SECTION ON GASTROENTEROLOGY AND PROCTOLOGY

CHAIRMAN, DR. SIDNEY K. SIMON, OF NEW ORLEANS.
SECRETARY, DR. FRANK SMITHIES, OF CHICAGO.

Value of the String Test in Cases of Gastric and Duodenal Ulcer.—Dr. Jacob E. Meengs, of Grand Rapids, Mich., in a comprehensive paper on this subject said that the extensive use of the string test prompted a presentation of its relative merits as a routine test in ulcer cases. He described the technic

The New Method of Hay Fever Treatment



THE tendency is increasing, in recent years, to give a greater number of doses, of higher protein content, at shorter intervals (12 to 48 hours).

In Hay Fever Treatment, 15 doses have come to be regarded as the minimum that should constitute a treatment, while some authorities recommend 20 doses or more, as indicated, and treatment being continued through the hay fever season.

The Mulford Pollen Extracts are supplied in such forms and strengths as afford greatest convenience in measuring dosage and making injections.

Easy to Use for General Practitioner or Specialist

Mulford Pollen Extracts, for the four principal pollen groups (ragweed, timothy, lamb's quarters and wormwood) are supplied as follows, in measured, individual doses and in ready-to-use containers:

15-dose Treatment Package (Doses 1 to 15)
First Series Package (Doses 1 to 5)
Second Series Package (Doses 6 to 10)
Third Series Package (Doses 11 to 15)
Fourth Series Package (Doses 16 to 20)
Also in 5 cc vials.

Mulford Pollen Extracts are the specific pollen proteins in refined form, accurately standardized in terms of protein units (one protein unit is comparable to four pollen units).

They are stable in solution, thus avoiding all inconvenience of diluting or mixing before use.

Mulford superior quality is typified in these products—in the specificity and uniform strength of the extracts and in the convenience of the packages.

FREE CUTANEOUS TESTS AND LITERATURE

of giving the string test and the interpretation of its findings, and discussed the cases which were x rayed previous to giving the string test. The x ray and string test were considered as respective aides to one another. Adverse criticisms of the string test were discussed, also the findings in normal individuals. The author closed his paper with a resumé of string test findings in positive and negative cases.

Clinical Variations in Negro Proctology, the Venereal Factor.—Dr. Curtice Rosser, of Dallas, said that two controlling factors accounted for a very large group of anorectal cases in the negro race. The first factor, the fibroplastic diathesis, was discussed in a contribution before the section two years ago. The second factor was responsible for considerable general pathology in the race—the incidence of venereal disease of every variety. Among the anorectal lesions seen in dispensary proctology among negroes primary and tertiary were lues, gonorrheal proctitis and anal chancroid. Incidence and methods of recognition were described, with a description of lesions and treatment.

The Clinical Effects of Abnormalities in the Portal Circulation on the Gastrointestinal Tract.—Dr. J. F. Montague, of New York, said that the clinical effects of deviations from normal portal circulation were not completely appreciated seems evidenced by the fact that certain gastrointestinal ailments were as yet but vaguely understood. As such may be mentioned mucous colitis, intestinal indigestion, flatulence, stasis, constipation and hemorrhoids. Indeed, not infrequently the latter condition was considered the chief or only clinical effect of portal plethora. That this view was erroneous Montague believed might be found in a study of the hemodynamic factors of the portal system. Such a study would also afford an explanation of the other conditions mentioned.

Treatment of Hemorrhoids.—Dr. J. Rawson Pennington, of Chicago, Ill., said that some years ago he made a new classification of hemorrhoids into —infective and noninfective; based, of course, on the relative virulence of the infection in the pile tumor. Since all examples were either infective, or potentially so, it was essential that the focus be extirpated. A slide was shown from the stump of a former hemorrhoidectomy done by one of the "closed" methods; bacteria and a round cell infiltration could be seen in the field. This patient was supposed to have "gastric ulcer," and was due for a gastroenterostomy, but the gastric symptoms promptly subsided after removal of the pathological condition, and free drainage was provided. A crater like opening was to be seen in the apex of the field, evidently Nature's mode of permitting the excess products of infection to escape. The same must hold good for other "closed" operations when the infection was virulent enough, or of the type to need such a vent, and the author said he was told by fellow surgeons that the scar after clamp and cautery operations frequently opens.

If the infection be of low grade or only of the toxemia producing type, such infected base may continue to smolder, giving off toxins, which passed into —and continuously poisoned—the system, occasionally with dire results, the same as from an infected tooth or tonsil. (It was passing strange, he said, that focal infection from the rectum and anus is seldom or never alluded to in the myriads of articles on this subject of late years. For a long time the author has insisted that the lower bowel was nearly as frequent a site of the foci as the opposite end of the gastrointestinal canal.)

Total removal of the infected base and good drainage was very essential. Simply removing the top of the mass, sealing in the infected base, and leaving Nature to open the eschar for escape of the infection, was certainly not good surgery. Hence twenty-six years ago, after a thorough trial of the ligature and the clamp and cautery methods, the author devised his "open" operation, by total excision, which has given complete satisfaction after use in several thousand patients. The unsatisfactory results met with after other plans such as severe pain (especially during defecation), loss of control, stricture, abscesses, fistulæ, exuberant cicatrices, ectropion, recurrences, etc., have one and all been notably absent. Moreover, the stay in hospital instead of being one to three weeks, was reduced to one to three days.

The author's second choice was the injection plan or its analogue—electrolysis.

Spastic Esophagus and Mucous Colitis: Studies of the Etiology and the Treatment by Progressive Relaxation.—Dr. Edmund Jacobson, of Chicago, said that laboratory investigations made at the University of Chicago have given evidence that mental and emotional activity may take part in the production and maintainance of esophageal spasm, at least of the mild type. Other experiments have shown a relationship between mental activity and contraction of skeletal muscles, for with advancing muscular relaxation mental and emotional activity dwindle or cease. It has been shown also that during extreme muscular relaxation the reaction of an individual to a painful electric shock applied to the finger tips tends to be diminished both subjectively and objectively. Not relaxation in the usual popular sense was meant, but an extreme form that required months to cultivate. These experiments have led the way to the development of a method called progressive relaxation, which has been shown to diminish central nervous activity as tested by the flexion reflex and other reflexes. In practice this method is tested by the diminution of the kneejerk during advanced relaxation. It has been shown that by this method at least one type of alimentary spasm, esophagus, may be diminished in a number of individuals. This method apparently acts through the reduction of reflexes of skeletal musculature thereby bringing with it a corresponding reduction of proprioceptive impulses and of reflex stimulation of the alimentary tract. Clinical observations now suggest that this method may be successfully applied to the treatment of mucous colitis.

Calcium, Carbon Dioxide and Chloride Content of Venous Blood in Cases of Gastric Ulcer Treated with Alkalis.—Dr. Sara M. Jordan, of Boston, reviewed briefly the literature on acid base balance and alkalemia, and referred to the normal variations in the acid base balance. The occurrence of alkalemia in a small percentage of gastroduodenal ulcer cases treated by the Sippy method was noted. The author said that fifty cases of gastroduodenal

ulcer were studied with reference to the content of calcium, chloride and carbon dioxide in the venous blood during the first three weeks of treatment by the Sippy method. A few observations were made during the subsequent months while patients were still under treatment. These results were compared with ten normal cases studied for a period of three weeks. It was concluded that the variation was greater in those cases treated with alkalis than in normal cases without alkalis. The maximum levels for calcium and carbon dioxide were higher. Three cases showing alkalemia were discussed.

Chronic Ulcerative Colitis.—Dr. Louis A. Buie, of Rochester, Minn., spoke of the appearance of the rectal and sigmoidal mucous membrane in chronic ulcerative colitis, as seen through the sigmoidoscope. He said the impressions were based on examinations made of 473 patients. Pathologically the disease was divided into an active and quiescent period. The former was divided into four distinct stages: 1, period of hyperemia usually seen during the acute onset and in which the mucous membrane was diffusely inflamed and bled on the slightest trauma; 2, edema in the hyperemic mucous membrane which smoothed out the folds chiefly in the sigmoid and appeared as a boggy thickened and inflamed mucosa; 3, miliary abscesses appeared in the hyperemic and edematous mucous membrane; these abscesses averaged about 1 mm. in diameter and were not identical with the lymph follicles, and 4, rupture of abscesses leaving miliary ulcers with yellow bases containing, almost in pure culture, a lancet shaped diplococcus (discovered by Bargen) and which was in all probability a specific cause of the disease.

After the stage of miliary ulcers a tendency toward remission was manifested and was characterized by gradual disappearance of hyperemia and edema and a lessening of the tendency to bleed on trauma. The final stage of remission was reached when the mucous membrane was glazed and pitted with punctate scars. After successive attacks a characteristic contraction of the lumen of the bowel appears.

SECTION ON RADIOLOGY

CHAIRMAN, DR. A. C. CHRISTIE, OF WASHINGTON.
SECRETARY, DR. W. J. HUBENY, OF CHICAGO.

Osteochondritis or Epiphysitis.—Dr. A. C. Christie, of Washington, D. C., in his chairman's address reviewed our knowledge of the pathological condition which had been variously named osteochondritis, epiphysitis, and osteochondropathy, and which in special regions of the body had been given many descriptive designations, or had been named after its discoverer or discoverers. The paper opened with a brief description of the anatomy of the epiphyses and a consideration of the etiology of epiphysitis, and was followed by a consideration of the following pathological conditions, all of which are now classified under the general head of osteochondritis or epiphysitis: 1, osteochondritis deformans juvenilis coxæ (Legg-Calvé-Perthes's disease); 2, Osgood-Schlatter's disease of the adolescent tibial tubercle; 3, Köhler's disease of the tarsal scaphoid; 4, Köhler's disease of the second metatarsus; 5, vertebral epiphysitis; 6, epiphysitis of the os calcis; 7, osteochondritis dissecans of König.

Pathological Changes in Lung Tissue as the Result of Foreign Bodies of Long Sojourn.—Dr. W. F. Manges, of Philadelphia, said that the length of sojourn of a foreign body in lung tissue varied from a number of weeks to many years. There was a remarkable variation in the reaction to the presence of foreign body on the part of the lung, both as to time of onset of such reaction and as to the severity and extent of it. The changes in the lung tissue were mostly the result of infection. The foreign body not only interfered with drainage but also prevented healing or the natural control of infection. The end results were fibrosis, cavitation, bronchiectasis, pleuritis, pneumothorax, empyema, intermittent hemorrhages, fistulæ, malignant degeneration. The lesions were distal to the location of the foreign body. Many cases were mistaken for tuberculosis and treated as such. It was remarkable, he said, how infrequently tuberculosis developed. From the character of the changes seen in positive foreign body cases, he believed that many of the cases of bronchiectasis and similar chronic changes were of foreign body origin, the foreign body being of the nonopaque variety, and should be treated as such. Long forgotten facts in the history were often brought to light after diagnosis by röntgen rays. Bronchoscopic insufflation of bismuth or iodized oil was of the utmost value in helping to make x ray studies precise in result. The paper was accompanied by lantern slide illustrations.

New Position for Making Radiographs of the Mastoid.—Dr. Amédee Granger, of New Orleans, La., said that he had worked out this position to replace the one recommended by Arcelin, which was found difficult and tedious to use and which cannot be used at all with infants, unruly children, the very old, the very weak, or the septic and those who have short thick necks. Like the Arcelin it keeps the weight of the head off the ear, and mastoid region, and radiographs made with it are practically identical in appearance with those made in the Arcelin position. They show clearly and without superimposed shadows the superior semicircular canal, the course of the internal and external auditory canals and the periantral, zygomatic and tip cells. The three groups of cells can be quite satisfactorily differentiated. Like the low position, it can be used with all patients except infants and unruly children, and it is more comfortable to them.

X Ray Studies of the Appendix, Cecum and Ascending Colon.—Dr. Benjamin H. Orndorff, of Chicago, said that the appendix and first portions of the colon were frequently the seat of important pathology which was not distinctly inflammatory in character. The significance of a pathological appendix, a fixed cecum and ascending colon seemed not to be generally appreciated. In addition to a consideration of the history, physical and laboratory findings, the investigation must determine also, location, fixation, mobility, position, size of the lumen, filling defects, capacity for filling and emptying, and tenderness to palpation. The detection of these findings was scarcely possible without the aid of the x rays. The technic of such examinations was greatly facilitated by certain methods and apparatus which were illustrated.

Historical Medicine

Medical Notes from Swift's "Journal"

LOUIS J. BRAGMAN, M.D.
Syracuse, N. Y.

Jonathan Swift, born in Dublin in 1667, will always be remembered for his classical lampoon, *Gulliver's Travels.* Among the other important works of this critic, reformer, and pamphleteer are *The Tale of a Tub,* which has been designated the wildest and wittiest satire of the eighteenth century; and *The Modest Proposal,* in which is offered the mild suggestion that the people of Ireland, in order to relieve themselves of their dreadful poverty, should sell their children as food to the rich.

His *Journal to Stella* consists of an intimate, Pepysian series of sixty-five letters to Esther Johnson, a lifelong friend. Scattered throughout the running comments on people with whom he came in contact are found some random references to the medical profession of the day. The period covered by the letters is from 1710 to 1713.

He dined on one occasion, he relates, with Dr. William Cockburn, a Scotchman born in 1669, who invented an electuary for the cure of fluxes. This shrewd physician, who had been stigmatized "an old, very rich quack," wrote, in 1729, a biting sketch called *The Danger of Improving Physick,* as a direct jibe against the academicians who envied him the fortune he had made.

The "kindly Arbuthnot, the Queen's physician," was an intimate and constant friend of Swift. A Fellow of the Royal College of Physicians, and its Harveian orator in 1727, John Arbuthnot was distinguished no less for his literary attainments than for his scientific works. Swift introduces him on several occasions:

"Arbuthnot made us all melancholy, by some symptoms of bloody u(rin)e: he expects a cruel fit of the stone in twelve hours; he says he is never mistaken, and he appears like a man that was to be racked tomorrow."

Another time he wrote: "Arbuthnot says he hopes my strained thumb is not the gout; for he has often found people so mistaken."

An invitation was extended him to dine with Sir William Read, a popular quack who had advertised largely in the *Tatler,* and who had been satirized in number 547 of the *Spectator.* Addison here ridicules the fact that the patients of this "eminent physician" were solicited to announce "the several distempers under which they laboured," and the cures which resulted, in "public prints."

Read was nevertheless knighted in 1705, for his services in treating gratis many seamen and sailors for blindness, and was later appointed Oculist to the Queen. After his death in 1715, his wife continued his practice.

Swift was well acquainted with Dr. Samuel Garth, best known for his satirical poem, "The Dispensary," written in 1669; and with Charles Barnard, Seargeant-Surgeon to the Queen, and Master of the Barber-Surgeon's Company. He dined several times with Dr. Hugh Chamberlen, the younger, a Fellow of the College of Physicians and Surgeons, and one of its censors for a number of years.

John Radcliffe, a well known physician and wit, who was denounced as a too clever empiric, treated him in 1711 for his attacks of dizziness. Others to receive mention are Dr. John Feind, physician to the Queen during the reign of George II; and Thomas Lawrence, First Physician to Queen Anne, and Physician-General to the Army.

In addition to these brief notes on members of the medical profession, the *Journal* contains an occasional witticism of pertinent interest. For example, in speaking of an affliction which had attacked the Lord Treasurer, Swift humorously remarked:

"He has had an ugly return of the gravel. 'Tis good for us to live in gravel (referring to the Kensington Gravel Pits, a very famous health resort), but not for gravel to live in us; a man in this case should leave no stone unturned."

Punning, even as now, was then a popular form of amusement:

"I'll tell you a good pun. A fellow hard by pretends to cure agues, and has set out a sign, and spells it *egoes;* a gentleman and I observing it, he said, 'How does that fellow pretend to cure agues?' I said I did not know, but I was sure it was not by a *spell.*"

There are numerous bits of gossip pertaining to the various ailments and accidents and operations which befell his many acquaintances, but they are worded unfortunately in the form of curt conversation and small talk, and hence must lose their significance unless read in the Journal itself. However, in reference to one condition, and that of which he himself was the victim, he has submitted a very satisfactory and complete clinical history. On March 28, 1712, he wrote:

"I have a pain these two days exactly upon the top of my left shoulder. I fear it is something rheumatic, it winches now and then. Shall I put flannel to it?"

The next day he was no better.

"I am plagued with these pains in my shoulder; I believe it is rheumatic. I am got into bed, and have put some old flannel, for want of new, to my shoulder, and rubbed it with Hungary water (a mixture of distilled water and rosemary flowers). You must know I hate pain, as the old woman said."

He follows with a minute description in his note on April 8th:

"All these days I have been extremely ill, though twice I crawled out a week ago; but am now recovering, though very weak. The pain increased with mighty violence in my left shoulder and collar-bone, and that side my neck. On Thursday morning ap-

peared great red spots in all those places where my pain was, and the violence of the pain was confined to my neck behind, a little on the left side; which was so violent that I had not a moment's ease, nor hardly a minute's sleep in three days and nights. The spots increased every day, and bred little pimples, which are now grown white, and full of corruption, though small. The red still continues, too, and most prodigious hot and inflamed. The disease is the shingles. I eat nothing but water gruel; and am very weak, but out of violent pain. The doctors say it would have ended in some violent disease if it had not come out thus. I shall now recover fast. I have been in no danger of life, but miserable torture."

But throughout the month of April he was no better. The spots became inflamed, and then very irritable, and finally ran into three or four large sores resembling blisters. Even in May he was still enduring some pain in the shoulder:

"I keep a flannel on it, and rub it with brandy, and take a nasty diet drink. I still itch terribly, and have some few pimples; I am weak and sweat; but I think my pain lessens. The doctors said they never saw anything so odd of the kind; they were not properly shingles, but *herpes miliaris,* and twenty other hard names."

It was not until July, four months from the onset, that he felt he had fully recovered from the effects of the ailment.

Scattered throughout the *Journal* are references to spells of giddiness which periodically attacked him. In addition he suffered at various times from deafness, impaired vision, muscular twitchings, and paralysis of the muscles of the right side of his mouth. He received the stigma, for the singularity of his actions, and the violence of his temper, of "the mad parson." It is related further that on observing an elm that had been blasted by lightning lying along the roadside, he remarked:

"I shall be like that tree, I shall die at the top."

This prediction ultimately came true, for in 1738 he developed signs of acute mania, necessitating constant supervision. After a long period of apathy he died in October, 1748.

It is supposed that he refrained from marrying the Stella of his *Journal* because the insanity of a paternal uncle and his own significant symptoms led him to be fearful of perpetuating a neurotic strain. That mental problems were uppermost in his thoughts is further evidenced in his selfcomposed obituary poem, "On the Death of Dr. Swift," which relates that:

"He gave the little wealth he had
To build a house for fools and mad;
And showed by one satiric touch
No nation needed it so much."

Medicine According to the Talmud

SOLOMON R. KAGAN, M.D.
Springfield, Mass.

(*Concluded from page* 461)

The Talmudic physicians, recognizing the importance of the digestibility of food, urged regulation of the meals and proper amounts of food (64).

Many Talmudic statements were devoted either to prevention of disease or to increasing body resistance to conquer the causative factors of many maladies. The Talmudist regarded constant dry climate and mineral springs as beneficial to health. The damp ground was improved by means of planting certain "Tossio" (65). Hot baths were recommended for the double purpose of drinking and bathing. Cold and warm baths were considered by some of the Talmudists as remedial measures of utmost importance. These baths according to the Talmud caused not only relief of pain in inflammation by producing contraction of the bloodvessels, but also are of great value as a tonic stimulant in increasing the power of resistance of the organ. They recognized the local use of washing the hands and feet for its influencing of deeply seated organs and as a therapeutic agent of great practical value (66). They proposed to apply alternate temperatures for the purpose of increasing the tone of the system and stimulating the vital centres to increased activity, and to prevent the person from the tendency of "catching cold." They also taught that a hot bath should be followed by a cold shower: this is likened unto heated iron being allowed to cool in order to lend strength to the metal (67).

Hydrotherapy was highly recommended as a preventative and a curative. Cold water sponging in the summer and winter is of benefit to the stomach (68). Rabbi Chanina recommended frequent bathing followed by a rubdown of balsam as a tonic and sedative to the body. Since he applied this rule to himself, in spite of his eighty years, he felt strong, healthy and vigorous (69). "Warm baths are of greater importance than medications" (70).

It is known that in certain diseases an incision of a bloodvessel with the withdrawal of a certain amount of blood is indicated. In the Talmudic epoch the chemical composition of the blood was unknown. They did, however, suggest the presence of certain poisons in the blood, and for the purpose of the diminution of these poisons they also advised venesection or removal of blood in moderate quantities (71).

Running was regarded as harmful for the sight; climbing stairs harmful for the heart; but moderate physical exercise was considered beneficial (72). The Talmud advised everyone to learn to swim, and also to acquire a trade (73). The Talmud said: "Even if your wife has a hundred servants, she still ought to

do some work herself, for idleness is the downfall of all women, and leads to excesses and maladies" (74).

It is of interest to know that the Talmud had scientifically explained the physiology of menstruation, mostly in accordance with the views of the modern physiologists. The Talmud also discussed various questions of obstetrics. For about three decades a Vienna professor explained that formation of sex in the fetus depended on the pregnant woman's diet. The Talmud, however, explained this phenomenon in connection with the position of the ovum, i. e., the place where the ovum became implanted (75). The Talmudists believed that the diet of a pregnant woman had an influence upon the strength, character, and complexion of the child (76).

Being aware of the importance of a sound body for a healthy soul, the Talmudists laid down the following hygienic rules:

Sudden changes in temperature are decidedly harmful, and the cause of many diseases (77). A cold drink in a heated state is dangerous. Sleeping on the floor or in damp places is harmful (78). The sunshine is a real remedy (79). The patient feels better in the morning due to the sunshine (80). Exercise is of greatest value for the health (81). Rav said to his sons: "Do not take medicine; do not jump; do not extract teeth; and do not annoy the snake" (82). Marriage was advised at the age of eighteen years (83). "The eye is like a princess and it hurts here to be touched by a hand that has not been washed three times," said Rabbi Nathan. Bathing the eye in cold water in the morning and bathing the hands and feet in warm water at night are the best medicines for the eyes," said Samuel (84).

The rabbis taught: "One may wash his body in the waters of Gror and Tiberias, but it is not allowed to bathe oneself in water used for floating flax." "One should always endeavor to seek a dwelling in a city of recent settlement" (85). The impure air of large cities is harmful to the health (86).

GENERAL TREATMENT ACCORDING TO THE TALMUD

The methods of treatment practised by the Talmud bear the seal of the old epoch. Some of these, however, are practised moderately at the present time. The Talmud said: "The door which is closed for God's deeds is open for the physicians" (87). Therefore the Talmudists advised praying to God for recovery (88). The rabbis and sages prayed for the cure of patients (89). However, they also had confidence in medicine. The physician was permitted by God to treat all diseases (90). In emergency cases they were allowed to cure even on the Sabbath (91).

The Talmudist believed that hygienic measures should take first place in the method of treatment. In this connection they attribute to drugs a very secondary rôle, paying particular attention to diet and regular environment of life. The methods of treatment practised by the Talmudists were partly by the administration of certain drugs, and partly by the use of remedial measures other than drugs, as foods for the sick, climatic treatment, cold sponging, counterirritation, heat, inhalation, drawing of blood, mineral springs and rest cures (92).

The Talmud prescribed many drugs (herbs and minerals) for therapeutic purposes. But the nomenclature of the drugs at the time was so different from that of the present time that it is difficult to decide which drugs of the present pharmacopœia they applied then. Besides, the pharmaceutical preparations were not strictly correct by weight and measures, but they ordered approximately in general forms, not designating the dose. Therefore, the remedial measures other than drugs prescribed in the Talmud are of more practical and scientific value.

Many methods of treatment which are the achievements of modern medicine, discovered by long experiments, laboratory investigation and research, were briefly discussed two thousand years ago by the investigating spirit of the Talmudists on the grounds of hypothesis and logical judgment. A few examples of methods of treatment according to the Talmud are given here:

Since stomach troubles have been the greatest bane of mankind the Talmud laid much stress on the care of the bowels. They paid particular attention to diet and physiology of peristalsis. The Talmudists, discussing the causes of the troubles of the digestive system, agree that it is due to a number of causes, the most common of which is sedentary life, laziness, overeating and overdrinking. In this connection, they advised the consuming of easily digested food; eggs must be eaten soft boiled; vegetables and fruits should be eaten freely; plenty of water during meals and systematic massages regularly applied (93).

For constipation, the Talmud advised the free use of vegetables, lettuce, and radishes in summer as well as winter, because the radishes churn the food in the stomach; lettuces overturn it and cucumbers extend the gut (94).

They also used a composition of certain herbs as a purgative. The latter was recommended not to be given to a pregnant woman as it was dangerous (95).

To relieve the stomach pain the rabbis advised: "One may warm a sponging cloth and put it upon his stomach, but he must not do so with a boiling hot vessel, for this is dangerous" (96).

Rabbi Chanina advised carshun for relief of pains in the stomach (97). The Talmudists suggested a remedy *Coss Ickrin* for icterus (98).

The Talmudists used a grain of pepper or cinnamon to take away any bad odor of the breath (99). A grain of salt or the eggs of grasshoppers were regarded as remedies for toothache (100).

As a preventive and curative measure for neurasthenia the Talmud proposed cold baths and mineral waters for both drinking and bathing (101).

Psychopathia (and disease of the mind) was treated by suggestion and hypnotism (102). For the cure of nosophobia (an exaggerated fear of disease) concentration of the patient's mind on prayer of faith and on science in order to attract his imagination was recommended. "If you suffer from headaches study the Torah," said the Talmud (103).

The Talmudists were familiar with the operation of extraction of the fetus through an incision made in the abdomen (104). It is also mentioned the operation for imperforate anus in the new born (105). They used to freshen up the border of old wounds in order that union might be effected (106). Extirpation of the spleen was successfully performed (107). They used artificial teeth made of hard wood,

bone, gold and silver (108). They used to wear tunics over their dresses during an operation (109). In major operations the patient was given an anesthetic (110). Venesection was produced as a therapeutic and preventive measure by means of leeches or cupping. After the operation of venesection a dietetic regime was prescribed (111). Many surgical diseases such as fractures, dislocations, etc., are discussed in the Talmud (112).

As a remedy for heart trouble the Talmudists prescribed an ointment prepared of cumin, soap, mint (fern), wormwood, cedarblossom and hyssop. All these were to be dissolved in wine. The same dissolved in beer was useful against pain in the uterus. The same dissolved in water was of benefit for gas in the stomach (113). For bronchitis and heart pains they recommended that one drink warm goat milk every morning (114).

Samuel treated eye maladies by drops, ointments, and cold applications (115). It was allowed to cure on Sabbath eye diseases if there was danger of losing one's eye, because the optic nerves are dependent on the heart (116). It was also allowed to treat on Sabbath a secreting eye, a wounded eye, an eye covered with blood, and an inflamed eye. The rabbis advised to bathe eyes and to apply human milk and white of an egg for preparation of a salve for a sore eye (117).

For earache, R. Johanan suggested the applying of loins. Rabbah said that all fluids are injurious to the ear, except the water from loins. Thus, take the kidney of a woolless sheep, cut it crosswise, place it on burning coals and collect the water that begins to flow from it. This water, when it is neither too cold nor to warm syringe into the ears. Or one may rub in the ears with the molten fat of a big chafer. The following is another good remedy for earache: fill the sick ear with olive oil and warm it, taking, of course, precautions against burning the patient. It must also be noted that for discharging ears the remedies must be dry, while for aching ears that do not secrete moist applications must be used (118). Other rabbis treat with an application of a certain cotton (119). Crutches and various other orthopedic appliances were known to the Talmud (120). They practised trephine and intubation of the larynx upon animals (121). In case of loss of substance of the cranium they used a plate for plastic operation. They used a certain instrument for the correction of prolapsus recti. They used to reposit the abdominal viscera by means of relaxing the abdominal muscles and by closing the wound with sutures (122). Intestinal parasites were expelled by urigo (123). In the treatment of overeating they applied ipecac (they called it ipectosin) to produce vomiting (124). They prescribed opium (they called it opiun) as analgesic and hypnotic. Large doses of them were considered dangerous (125). Most of the amputation or cauterization was made on the lower extremity (126). Sunstroke was treated by "trick" which was composed of a certain drug with snake's flesh (127). Rabbi Huna said: "If one swallowed a leech or bee drink some strong vinegar" (128). Samuel treated diseases according to homeopathy (129). The sting of a lizard they cured with warm medicines, that of a hornet with cold ones. Likewise warm medicine is recommendable for the pricks of thorns, and cold ones for chapped skin; to reverse is dangerous. A high temperature should be reduced by the application of radishes (130).

As a remedy for cough, Rabbi Papa advised to fill a new pitcher with water, put therein a spoonful of honey and a rue (plant) (131).

For the treatment of a carbuncle Rabbi Saphra suggested to put a rue with honey or radishes with strong wine upon it. While these remedies are being prepared, put meanwhile on the sore a white or red grape, according to whether the sore is white or red. Rabbah said: A tumor is a sure symptom of inflammation. He recommended to hit upon it with the fingers sixty times, then open it crosswise. If, however, the tumor had a white spot on the top, all this is not necessary, as then it was not dangerous (132).

In order to stop bleeding a prominent physician and rabbi Samuel, advised to apply cress dishes mixed with vinegar (133). Other rabbis recommended the application of cold water (134).

HOME REMEDIES ACCORDING TO THE TALMUD

It is known that some home remedies are used even at the present time, having been investigated and recognized by science as valuable. The Talmud, too, mentions some of the socalled home remedies which were taught to the masses and were known as popular remedies. The form and order of their use is characteristic of the old Talmudic epoch. The following medical directions recommended by the Talmud are an illustration of them:

Women may go out with a Kutana stone, to prevent miscarriage. The tooth of a live fox was recommended to prevent sleep, and that of a dead one to cause sleep; a nail from the gallows where a man was hanged is remedy for swelling (135).

Rabbi Judah said: "That Holy one has created nothing useless in the world. He created the snail as a remedy for a sore, the fly for the sting of a wasp, the mosquito for the bite of a serpent, the serpent for the mange, and the lizard for the bite of a scorpion" (136).

The following five are apt to strengthen one's memory: bread baked on coals, and particularly the consuming of the coals themselves, soft eggs without salt, the frequent drinking of olive oil, of wine flavored with spices, of water left after its use for a dough. According to others add this, the consuming of wheat bread. The following five objects are conducive to one's forgetting his studies: The eating of the remnants of the mice's or cat's food, of the heart of a cow, the frequent consuming of olives, the drinking of the water left from ones own washing, and finally, the bathing of one's feet one kept on the other. According to others, putting of one's clothes under one's head while sleeping (137).

Rabbi Assi advised for pain in the abdomen that seven red grains, usually found in the washhouse, be put in the linen collar of an old shirt which should be bound with a cord made of the hair of a cow; then immersed in white pitch and burn, the ashes thereof he should apply to the sore place and relief would follow. While the preparation of this was going on, he might apply seedless blackberries. This remedy, however, is effective only in case of external pains; for internal abdominal pains, grease the sore place with the molten fat of a goat that has not yet borne

any offspring, or burn three pumpkin leaves dried in the shade and apply the ashes; also almond worms or olive oil and wax may be applied, in summer on linen, in winter on cotton (138).

CONCLUSIONS

1. The medical instructions and directions of the Talmud are so positive and so concrete that it is quite evident that the Talmudic physicians were familiar with the manifestations and treatment of local and constitutional diseases. The medical knowledge and methods of treatment used by the Talmudists were based not only on hypotheses and traditions, but also on observation, dissection, and experiments upon animals.

2. The Talmud contains no medical treatises as such. The medical subject is discussed and stated as far as it has a connection with the problems of rites and ceremonies. It regards the hygiene as a God's deed, as a ritual action.

3. The Talmudic medical statements have a great value from an historical point of view, being guides to the development of this subject, its different stages and its construction. The general Talmudic therapeutic considerations are of interest to the history of medicine, showing that many old methods applied by the Talmudists were strikingly like those with which medical science is occupied at the present time.

The references will be included in the author's reprints.

Hints for the Cure of Squinting in Young Persons

(*Published in London in August, 1772*)

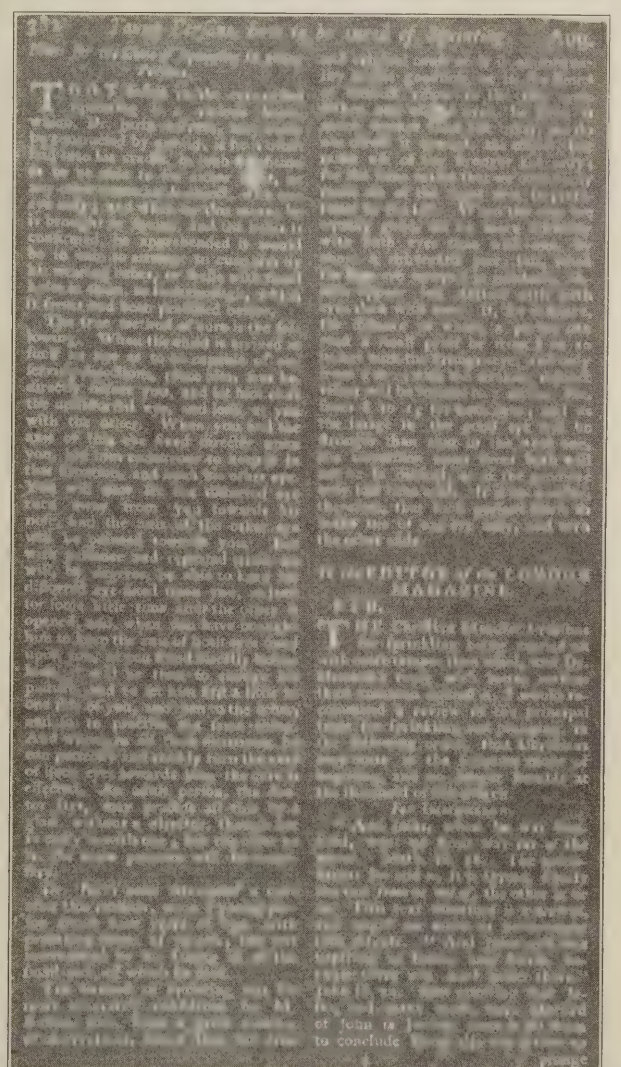
The following article on squinting appeared in *The London Magazine* or *Gentleman's Monthly Intelligencer* in August, 1772:

"That the defect in the eyes is a vicious habit, which, Dr. Jurin observes, may easily be contracted by a child, if he is often laid into his cradle, in such a position as to be able to see either light, or any other remarkable object, with one eye only; and when by this means he is brought to squint, and the habit is confirmed, he apprehended that it would be in vain to attempt to cure him by his wearing tubes, or shells with small holes in them, to look through, which it seems has been practised before.

"The true method of cure is the following. When a child is arrived at such an age as to be capable of observing directions, place him says he, directly before you, and let him close the undistorted eye, and look at you with the other. When you find the axis of this eye fixed directly upon you, bid him endeavour to keep it in that situation, and open his other eye. You will now see the distorted eye turned away from you towards his nose, and the axis of the other eye will be pointed towards you. But with patience and repeated trials, he will by degrees be able to keep his distorted eye fixed upon you, at least for some little time after the other is opened, and when you have brought him to keep the axis of both eyes fixed upon you, as you stand directly before him, it will be time to change his posture, and to set him first a little to one side of you, and then to the other, and so to practise the same thing. And when, in all these situations, he can perfectly and readily turn the axes of both eyes towards you, the cure is effected. An adult person, the doctor says, may practise all this by glass, without a director, though not so easily as with one; but the older he is the more patience will be necessary.

"Dr. Jurin once attempted a cure after this manner, upon a young person about nine years of age, with promising hopes of success; but was interrupted by his falling ill of the smallpox, of which he died.

"The business of squinting was far more accurately considered by M. Buffon, who, from a great number of observations, found that the true and original cause of it is an inequality in the goodness, or in the limits of distinct vision in the two eyes. When one



Photographic reproduction of page of the *London Magazine* on which this article originally appeared.

of the eyes, he says, is much weaker than the other, we do not direct it towards the object, but make use of the stronger eye only; for the same reason that we make use of the right arm in preference to the left.

"When the eyes are equally good, we see more distinctly with both eyes than with one, by about a thirteenth part; but, when the eyes are unequal in goodness, objects appear less distinct with both eyes than with one. If, for instance, a distance at which a person can read a small print be from eight to twenty inches with the stronger eye, and only eight to fifteen with the weaker, distinct vision will be limited seven inches, viz., from eight to fifteen for both eyes; and as an image in the good eye will be stronger than that in the weak one. The impression upon them both will not be so distinct, as if the good eye only had been used. It is no wonder, therefore, that such persons chuse to make use of one eye only, and turn the other aside."

Contributors to the Science of Medicine

Frederick Ruysch

Frederick Ruysch was a great anatomist and gave a new impulse to anatomical research. He was born at the Hague, March 23, 1638, his father being secretary of the States General of Holland. He studied at Leyden for the medical profession and displayed a particular predilection for anatomy. He took his doctor's degree in 1664, returned to the Hague, married and entered into practice. It was not long after his return that Holland had a visitation of the plague. It raged with the greatest fury, and young Ruysch was selected by the government to take charge of the cases which occurred at the Hague. He performed this service to the entire satisfaction of his fellow citizens.

The talents of Ruysch are said to have been developed by accident. To repel the audacious and calumnious aspersions with which Louis de Bils attacked de le Boe and Van Horne, relative to Ruysch's proposed method of preserving bodies from putrefaction, he published in 1665 and again in 1687 his tract on the valves of the lymphatics which completely established his character as an anatomist of originality and research. The publication of this work so increased his reputation that he was in the succeeding year invited to the chair of anatomy at Amsterdam. He now determined to devote his life to this special branch of medical study and human and comparative anatomy became the objects of his closest attention. The art of injecting, which had been attempted originally by Eustachius and Varoli, was afterwards rudely practised by Glisson, Bellini and Willis. Reginald de Graaf was perhaps the first to employ the syringe to aid researches into the anatomical structure of the human body. He injected the spermatic vessels with mercury and variously colored liquors. Swammerdam, however, carried the art to greater perfection as he, employing melted wax with other ingredients, made the first approach to the refinements of modern anatomy. It is said that Swammerdam imparted his knowledge to Ruysch upon quitting the paths of medicine for the mysteries and superstitions of Bourignon. Be this as it may, by improving upon the idea of using substances which though solid might be rendered fluid at the point of injection, Ruysch carried the art to the highest point of perfection. His success in the injection of the bloodvessels was such as fairly to warrant the epithet "marvelous" which was applied to them by those who witnessed the results of the process. The extreme branches were so well filled as to give to the dead body the freshness of youth and to imitate sleep rather than "sleep eternal," at least so says a French historian of the period.

A striking instance of the success of Ruysch in the preparation of dead bodies by injection is recorded in the case of the English Admiral Berkeley, who was killed in an action between the English and Dutch fleets on June 11, 1666. It is related that the body of the admiral was rapidly advancing to a state of putrefaction, and was therefore, by order of the States General, submitted to Ruysch for injection, to prevent further corruption. So well did he succeed in this, that the body came out of his hand looking fresh, was transmitted to England and the operator was rewarded handsomely for the exercise of his ingenious talent. A museum containing dead bodies treated with such superlative skill could not fail to attract widespread attention and it was visited by the learned from all parts of the world.

The Czar Peter, in his journey through Holland in 1698, spent many days in the museum of Ruysch, partook of his frugal fare, and in 1717 arranged for the purchase of the collection for the sum of thirty thousand florins, and consigned it to St. Petersburg. The tale also goes that the Czar was so delighted with the preparations, that he could not refrain from kissing a dead infant which seemed to smile upon him.

But Ruysch put his knowledge to the furtherance of the science of anatomy and to the advancement of his own fame. By the application of this happy device he was enabled to demonstrate the arrangement of minute vessels in the interior of organs which had escaped the scrutiny of former anatomists. Scarcely a part of the human body eluded the penetration of his syringe and, of course, his discoveries were proportionally great. His close description of the valves of the lymphatics, although he admits that they had been observed by other anatomists, of the vessels of the lungs, and their minute structure; his researches on the vascular structure of the skin, of the bones, of the epiphyses and their mode of growth and union; his observations on the spleen, the glans

penis, the clitoris, and the womb impregnated and otherwise, were but a comparatively small part of his anatomical labors. He investigated the minute structure of the brain, he demonstrated the organization of the choroid plexus, he decribed the state of the hair when affected with Polish plait; he proved the vascular structure of the teeth; he injected the dura mater, the pleura, the pericardium and peritoneum; he laid bare to the sight and described the minute structure of the conglomerate glands, he investigated that of the synovial apparatus situated in the interior of the joints and he discovered several curious particulars relating to the lacteals, the lymphatics, and the lymphatic glands. In short, Ruysch did yeoman service in the cause of anatomy and indeed put his remarkable knowledge of the art of injecting dead bodies and his skilful application of this knowledge to good use.

In 1691 he published *Observationum, Anatomico-Chirurgicarum Centuria,* to which he added a catalogue of the rarities in his collection. In 1710 the *Thesaurus Anatomicus,* also the *Thesaurus Animalium,* and between the years 1717 and 1723 his *Adversaria Anatomico Medico Chirurgica. The Epistola Anatomicæ* were published in several parts at different times. The whole of his works have been collected and published in five volumes with title of *Opera Omnia Anatomico Medico Chirurgica* in 1721 and 1735. He is said to have claimed the discovery of parts noticed previously by other observers and was therefore involved frequently in controversy.

Anatomy of Dr. Frederick Ruysch
By *Johan van Neck* (1683) (*Amsterdam Museum*) *Hanfstaengl, Munich*

In fact, among men of the medical profession, no name as a controversalist in anatomical matters has occurred so often as that of Ruysch. But nothing can detract from his reputation as an anatomist or from his fame as an anatomical discoverer and a correct reviser of other men's discoveries. His art as an injector gave him an immense advantage over other delvers of his time into the mysteries of anatomy, and of this unique expert knowledge he availed himself to the full.

He made a number of important discoveries concerning the structure of parts of the eye and ear. He was appointed professor of physics in 1685, which chair he filled for forty-three years, when from a fall in his chamber he fractured his thigh bone and was disabled from further work.

Ruysch was well known in foreign lands. He was elected a Fellow of the Royal Society of London and was the successor of the immortal Sir Isaac Newton in the Academy of Sciences of Paris. He was also a member of the Academy of St. Petersburgh. He died from fever on February 22, 1731, having reached the patriarchal age of ninety-three years. His illustrious contemporary anatomist, Morgagni, although of a later generation, died at the advanced age of ninety years.

Ruysch possessed the confidence of the ministers of his country. He was their forensic physician and also presided over the establishment for midwifery. Like Boerhaave, another contemporary but of a later generation, Ruysch paid much attention to botany and dissected plants with the same precision as bodies belonging to the animal kingdom. He filled the botanical chair and excelled Morgagni in that he published a book at the age of ninety. At eighty years of age he had vitality and enthusiasm enough to commence the formation of another museum to take the place of the one sold to Czar Peter, and moreover, he succeeded in his object and even made a catalogue of the collection.

It is said that no collection ever contained such specimens as the collections of Ruysch and that he had some means of preparing his specimens unknown to other anatomists not so highly perfected is obvious. His secret was buried with him and his son, Henry Ruysch, also a physician and the assistant of his father in the formation, died four years later and left the secret unrevealed.

Upon the death of Ruysch his museum was sold publicly and the King of Poland devoted twenty thousand florins to the purchase of a part which was at Wittenberg in the time of Haller.

The Oldest Medical Work in the World.—This is the Egyptian papyrus written by a Nile physician three thousand and five hundred years ago, detailing the methods to be pursued in dealing with fractured bones and head injuries. Forty-eight hypothetical cases are described by the ancient physician and treatment prescribed. Dr. James F. Breasted, the Egyptologist, said that the author showed a knowledge of brain functions which was not rediscovered until the present century. In the forty-eight prescriptions by this medical man, only once does he depart from science or common sense in favor of magic. The New York Historical Society has recently announced its plans for publishing this work.—*N. Y. Medical Week.*

Editorial Articles

SANITATION AND DOMESTIC HYGIENE

There are always two sides to a question and it is arguable, although the argument may be specious, to debate the point as to whether good sanitation and effective domestic and personal hygiene are wholly advantageous to the inhabitants of a country. Europe is overpopulated to some extent, and Great Britain certainly, because the death rate has been reduced and not on account of a reckless birth rate. Sanitation has abolished practically in civilized countries the epidemics which at one time decimated population and which now provide to some extent a safety valve for overcrowded Asia.

It seems that the progress of domestic and personal hygiene will curtail the mortality and invalidity which now arise from the chronic diseases and if so what will then happen to Europe. Great Britain affords a striking example of the manner in which the safeguarding of infant lives adds to a population which is already too great for the country to support properly. It is generally believed that owing to the fact that more than three quarters of the population of Great Britain live in towns that her death rate is high. On the contrary, the death rate of Great Britain is much the same as that of this country and not far behind that of her Dominions. This result is almost wholly due to her success in saving infant life. France has been regarded for years as the country which would not produce enough children. As a matter of fact there is very little difference between the birth rate of Great Britain and France; the reason why France's population is almost stationary is because her death rate is so much larger. In short, France's sanitary measures are less effective and domestic and personal hygiene and especially infant welfare are less considered.

Thus from her very care for human life Great Britain is overcrowded and in existing circumstances economically handicapped, while France from her lack of care for infant life can support her population easily, and from the economic viewpoint is in the better position.

There is anther aspect of the situation which is worthy of notice, that although the death rate of the urban population of Great Britain is low, it is not now the case of the survival of the fittest. The general physique of the inhabitants of British towns has deteriorated. The individual has benefited, but it is doubtful if it is to the good of the inhabitants at large that so many more children should survive than the country can adequately support. It may be predicted that a way will be found out of the difficulty and in the meantime domestic and personal hygiene will proceed apace, the menace of the chronic disease will be largely removed and in twenty or thirty years' time the span of life will be lengthened by five years or so.

MEDICAL EDUCATION

It is sometimes well to retrace our steps and make a fresh start along old lines, and such would seem to be the case in medical education. We sometimes get the cart before the horse in education, and it is usually advisable then to unhitch that animal and put him in his proper place.

We may profitably examine our whole artificial machinery of general education with reference to whether or not it educates, before making a similar investigation of methods of medical education in particular.

We have somehow become imbued with the idea that because a man has had a college course that he is, therefore, better educated and more fit to study medicine. Nothing is more likely to be untrue.

A local alumni society of one of our "greatest" universities recently invited its members to its periodical meeting, offering as its total bill of fare, besides "plenty to eat," music by a jazz band, selections by a darktown quartet, cinema pictures showing alma's athletic prowess and "strong smoking," whatever this latter may be. Such is the way we were "educated" to spend our precious leisure hours and that we may be "cultured" physicians after we have passed additionally through the medical mill with all its superfluities and repetitions.

The most important question to be answered before taking up the study of medicine or anything else is "Do we really like it, and feel we are fitted for it?" We were once told, in dead earnest, by an aspiring premedic that he knew that he was cut out to be a doctor because he always found pleasure in dissecting his sister's dolls. Doubtless that man is now a skilful surgeon, but we wonder what besides? The old custom of spending a year or so in a physician's service by way of probationary experience was a splendid thing in more ways than one. It was Councilman, we believe, who said that the study of medicine was heaven, but its practice hell, and it is sad to have to follow, unwillingly or unwittingly, the example of Satan.

We are interested to note that Dr. Ochsner would revive the old custom. He suggests the following requirements for the practice of medicine:

Accredited high school education; two years' useful, character building and judgment forming work if possible under the guidance of an able general practitioner; four years' intensely practical medical education; one year intern service. Of the two years' apprenticeship he says:

One of the tragedies of life, not infrequently met with, is the case of a young man who has spent eight or ten years preparing for a professional career only to find that he is entirely unsuited for it, either temperamentally or otherwise, or that for some reason he fairly detests it. Some who find themselves thus situated assuage their sorrow and disappointment by marrying rich heiresses and are then usually permanently lost to medicine or any other life of service. The rest flounder along never satisfied and never satisfactory. This could all be very largely avoided if during the two years when they are accumulating practical experience and some of the wherewithal with which to pursue their medical studies, the medical student would spend his leisure time doing systematic reading under the guidance of a competent medical practitioner and be permitted to visit patients with such a one, and help him some in his work, much after the fashion of the old preceptor system. In this way he would have an opportunity to test his fitness and adaptability for the profession before spending many years and much money, only later often to find his mistake. The above scheme would give the student a chance to develop the habit of application and industry, to get some practical experience in life with an opportunity to develop judgment and resourcefulness and persistence, things the present day graduate needs so sorely. It would give him two years of earnings with which to pursue his medical studies and would make it possible for country boys again to enter the medical profession in greater numbers. It would also let the student finish his undergraduate studies by the time he is about twenty-five years of age. If he would now associate himself with an older, busy general practitioner for a couple of years he would be in a position to be a much more useful member of society than is the average graduate of today because he would better supply the needs of the times.

Of medical instruction he remarks: "What medicine needs is not so much more facts as a proper correlation of facts already known. As things stand today the undergraduate student is fairly overwhelmed with facts, the great majority of which are of little practical value." We are reminded of the first edition of one of the finest physiologies ever put into the hands of the medical student. In its first edition there was, at the end of each of the ten or so chapters, a summary in italics of all that was really known or worth knowing in the preceding pages. This summary amounted to a total for the entire book of not more than fifteen pages. In later editions this summary has been omitted, and the reason is obvious. The sensible student got the essentials of the year's work from those few pages and did not waste his time mulling over the remainder of the text. It was fine for the pupil but bad for the professor.

ASEPSIS

As the theory of evolution dates far back in history but needed the overwhelming array of evidence laboriously set up by Darwin and Spencer to impress the average, and above the average, mind, on the subject, so asepsis was known glimmeringly and empirically long before Lister made the method rational. There is some ignorance for which the human race cannot forgive itself, but for ignorance of bacterial infection it had a good excuse in its poor eyesight, so far as the observation of microbes and their doings were concerned.

G. D. Hindley, in the *Nineteenth Century,* has called attention to the fact that antiseptic surgery is one of the "old lost arts" which is now recovered. Without any definite theory to go upon, any more than there was for the early observed effects of quinine in malaria, there were, early in the fourteenth century, "men, who not only knew that wounds could be healed without suppuration, but who practised continually, and with marked success, the cleanly letting alone of wounds which is the basis of aseptic surgery today. They used as a mild antiseptic application warm wine alone." Henry de Mondeville, who was the chief apostle of this method of treatment, "developed a definite theory of wound healing, and practised a method, which, in essentials, was indistinguishable from those of today." The neglect and loss of this method was "the greatest of all the misfortunes that have befallen the world. For it is hardly possible to imagine the heights to which surgery might have arisen in the course of six hundred years of the practice of aseptic methods."

De Mondeville got his idea from his teacher, Theodoric, of the Bolognese school, who rebelled against the universally accepted doctrine of Galen that suppuration of wounds was a natural condition, and must be promoted rather than prevented. Proceeding to the opposite course of treatment from the great Galen, he took every means to stop hemorrhage, he did not probe the wound, he did not enlarge it, and he did not insert packing or tents. He poured in warm wine, closed the wound at once with sutures, and applied fomentations of pads soaked in wine. "It cannot now be ascertained what was the alcoholic strength of the wines of Italy in the fourteenth century, but it may be assumed beyond all doubt that they were of sufficient strength to have some antiseptic power. And as compared with the greasy and septic preparations recommended by Galen and all his successors for a thousand years, warm wine has such advantages that it must be regarded as the predominating factor in the success of wound treatment" of these innovators.

"It is quite certain that nothing more than a high grade empiricism can be asserted for de Mondeville,

but he found that wounds could be made to heal aseptically by use of certain methods and he proclaimed the fact from the housetop with a great show of logical argument and ratiocination." He was indeed a bold man, for he dared say that "God did not exhaust all His creative power when He made Galen." It was a time when it was dangerous to oppose authority so universally accepted. The fundamentalists were all powerful. These two surgeons were antiseptic heretics against the medical faith fathered by Hippocrates, Galen, Paulus of Aegina and Avicenna. The new method was looked upon with grave suspicion and it practically passed away with the death of de Mondeville for want of another heretical champion. "Guy de Chauliac (the great surgical writer of the next generation) in 1363 speaks of the method with a certain contempt entirely rejecting the new theory of suppuration and the surgical world followed his leadership." Paracelsus rebelled against the Galenic teaching and declared that what wounds needed in the way of help to healing was nothing. He did not advocate the use of wine, however, and probably knew nothing of such treatment. With the death of Paracelsus in 1541 surgery, both in theory and practice of asepsis, " 'reeled back into the beast', and the long night of dirt and suppuration was never again broken until Lister at last made his great deductions from Pasteur's work on microbes."

LOCKE ON CHILD WELFARE

John Locke, gentleman and philosopher and author of the world renowned *Essay on the Human Understanding* and a contemporary of Sydenham, wrote in 1690 a book on child welfare under the title *Some Thoughts Concerning Education*. In his preface he says "I myself have been consulted of late by so many who profess themselves at a loss how to breed their children, and the early corruption of youth is now become so general a complaint that he cannot be thought wholly impertinent who brings the consideration of this matter on the stage, and offers something if it be but to excite others, or offer matter of correction. For errors of education should be less indulged than any. These like faults in the first concoction, that are never mended in the second or third, carry their afterwards incorrigible taint through all the parts and stations of life."

The first part of the book is devoted to the consideration of infant welfare, or, as he puts it, "Not what a physician ought to do with a sick and crazy child; but what the parents without the help of physick, should for the preservation and improvement of a healthy or at least not sickly constitution in their children. And this perhaps might be dispatched in this one short rule, viz., that gentlemen should use their children as the honest farmers and substantial yeomen do theirs. It was only the other day that a mother told me she had been paid a fine compliment on her children. A workman engaged in the house had been overheard saying to his mate, "Nice children, these, not like gentry's children."

He deals with the management of the child from the physical viewpoint. Warmth, bathing, fresh air, clothes, diet, sleep are all discussed in turn but it is in the psychological aspect of the question that Locke is most deeply interested. He was no believer in excessive punishment and could not conceive that any correction would be useful to a child, where the shame of suffering for having done amiss, did not work more upon him than the pain. Nor was he in favor of a flow of constant rewards and on this point thus expresses himself: "He that will give to his son apples or sugar plums, or whatever of this kind he is most delighted with to make him learn his book, does but authorize his love of pleasure and cocker up that dangerous propensity which he ought by all means to subdue and stifle in him. If you can once get into children a love of credit, and an apprehension of shame and disgrace, you have put into 'em the true principle, which will constantly work, and incline them to the right."

And again of tasks he said: "None of the things they are to learn should ever be made a burden to them or imposed on them as a task. Whatever is so proposed, presently becomes irksome; the mind takes an aversion to it, though before it were a thing of delight or indifference. Let a child be ordered to whip his top at a certain time every day whether he has or has not a mind to it, let this bit be required of him as a duty, wherein he must spend so many hours, morning and afternoon, and see whether he will not soon be weary of any play at this rate."

Locke understood clearly the mental outlook of the child. When a child by constant chiding and fault finding is made to feel hopelessly unworthy, he becomes abashed in spirit and loses all zest for his task and desire to succeed. Such treatment at school is frequently the cause of gross failure. The child becomes in a high degree self conscious and sinks with indifference to the bottom place in the class regarding all struggles to rise as futile.

Lastly the philosopher considers adolescence and manhood. It is interesting to know that the sons of men of substance in these spacious times were expected to marry and propagate at the age of twenty or twenty-one. On this point Locke sagely remarks. It would be no prejudice to his strength, his parts or his issue, if it were respited for some time, and he had to leave to get in years of knowledge, the start a little of his children, who are often found to tread too near upon the heels of their fathers, to the no great satisfaction either of son or father.

Locke knew a great deal of common sense child welfare and child psychology. In those days scientific psychology was unknown but a child now might be reared and educated successfully by following the precepts of Locke.

DEATH OF A GREAT WOMAN SURGEON

Dr. Louisa Brandreth Aldrich-Blake passed away recently in London at the age of sixty. She was born in 1865 and came of a family long settled in Suffolk on the east coast of England. Her father was a country clergyman. During her early education at home she evinced her aptitude for the career she followed subsequently. When only ten years old she set the leg of a neighbor which had been broken in an accident. After that there was no question as to what calling in life she was best fitted for.

On leaving Cheltenham Ladies' College she went to the University of London where she distinguished herself by being the first woman to become master of surgery. In 1892 Miss Aldrich-Blake took the London University M.B., with first class honors in medicine and obstetrics, at that time being a student at the Royal Free Hospital, the London School of Medicine for Women. She then took the B.S. with first class honors qualifying for the gold medal. After taking the M.D. and M.S. she joined the staff of the Royal Free Hospital as surgical registrar and anesthetist.

She was elected house surgeon to the new hospital for women known as the Elizabeth Garrett Anderson Hospital for Women, in memory of another great pioneer woman surgeon and surgeon to the Canning Town Women's Settlement Hospital. In 1914 Dr. Aldrich-Blake was appointed Dean of the London School of Medicine for Women, a position in which she exercised great influence upon the many thousands of medical women who passed through the school as students. During the war she helped to organize medical services and hospitals overseas. Over and above her surgical work she was very fond of travel and reading. After the war she made a tour of the large hospitals of America and will be remembered and regretted by those of the medical profession here with whom she came in contact. In the New Year Honors of 1925 she was created a Dame of the Order of the British Empire, an honor corresponding to that of the knighthood of that order. Miss Aldrich-Blake was almost the first woman in Great Britain to practise general surgery. For longer than a year before her end Dr. Aldrich-Blake had led a life of suffering which she never permitted to interfere in any way with her work. She bore both pain and disability with unflinching courage and cheerful equanimity and was active up to a few days of her death.

It is stated that only a few weeks before she passed away she worked often for sixteen hours a day, and performed as many as nine operations in one afternoon. Dr. Mary Scharlieb, the grand old woman of medicine, and herself, with Dr. Elizabeth Blackwell, Dr. Jex-Blake, Dr. Elizabeth Garrett-Anderson and Dr. Aldrich-Blake, a pioneer in medicine, stated in an appreciation of Dr. Aldrich-Blake published in a recent number of the *News of the World,* that the late dean of the London Women's School of Medicine was a great surgeon and invaluable Dean, but far more important than these qualities were those which made her an example as a leader among medical women and medical women students. "Her personality," added Dr. Scharlieb, "was both great and fine, and she will be held in most loving remembrance by all who knew her."

CAUSES OF DEATH

The report of the Surgeon General of the United States Army for 1924-1925 gives some interesting data on causes of deaths. There were the same number of deaths from disease in 1924 as in 1923, but eight more from violent causes. However, due to increase in the number of enlisted men, the death rate from all causes was lower.

The leading cause of death, as was the case in the previous year, was not infectious diseases, but suicide. There was the same number as in the preceding year. Second came tuberculosis, with a slight increase in number. Automobile accidents advanced from seventh place in 1923 to third in 1924. Balloon and airplane accidents again stood fourth, with a slight decrease in number. Twenty-one of these occurred among officers. During the eight year period from 1917 to 1924 there were 874 deaths in the army as the result of airplane accidents. This number is exclusive of the casualties of the World War. Of these deaths, 520 were among officers and 354 among white enlisted men. During the past five years the average annual death rate, calculated upon the Air Service strength, was for officers 26.95, and for enlisted men 2.61, and similarly in 1924 the officers' rate was 21.04 and the enlisted men 1.81. But the number of crashes per hour of flying hours for the heavier than air machines decreased from one crash to two hundred flying hours in 1921 to one crash in five hundred flying hours in 1924, and the fatalities from one to 955 flying hours in 1921 to one to 3,365 in 1924. The death rate for officers from injuries was almost twice as high as that for any group of enlisted men. Of the sixty-four deaths which occurred among them, twenty-nine were from disease, twenty-one from airplane and balloon accidents, six from suicide, four from automobile accidents, and four from other violent causes. Accidental drowning has been responsible for 818 deaths within the past ten years. Within the same time there have been 254 deaths from homicide. Automobile accidents have caused 463 deaths in the last eight years. There have been 1,015 suicides during the last ten years.

News Items.

Hospital Boat in Alaska.—About five thousand people on the Yukon River will have the benefit of medical service from a well equipped hospital boat, carrying a staff of a physician and two nurses.

Lye Bill Passed—The bill advocated by the medical profession, to safeguard the sale of lye and other corrosive substances, has been passed by the Senate. This provides that containers shall be marked conspicuously with the word poison.

Library Extension Service.—The state university of Indiana is planning a package library service to physicians in the state. Similar service is already provided by the University of Wisconsin, in cooperation with the state society, and also by the American Medical Association.

Occupational Disease.—For the five year period from 1920-1925, 3,241 cases of occupational disease were reported in Ohio. Dermatitis among rubber workers accounted for over eighty per cent. of all cases reported, with lead poisoning second—fourteen per cent.

Changes at Boston City Hospital.—The sum of $750,000 has been appropriated for a new maternity building at the Boston City Hospital, to be built at Concord and Albany Streets, and $250,000 has been appropriated for a research laboratory for the study of streptococcic infections. A building for outpatients and a new x-ray laboratory have recently been completed.

Exchange Professor at Johns Hopkins.—Robert W. Hegner, Ph.D., professor of protozoology at Johns Hopkins University School of Hygiene and Public Health, has gone to England for six months, to serve as exchange professor at the London School of Hygiene and Public Medicine. Dr. John G. Thomson, of the London school, will replace him at Baltimore.

Appointments in Police Department.—Dr. Patrick J. Murray, chief surgeon of the Police Department of New York City, has been retired, and will be succeeded by Dr. Daniel J. Donavan, who has been police surgeon for over twenty years. Dr. Joseph S. Baldwin has been advanced to deputy chief surgeon, and Dr. Harry C. deBrun has been appointed surgeon.

Research at Montefiore Hospital.—The establishment of the Hilda Stich Stroock research fellowship is announced by Montefiore Hospital for Chronic Diseases, New York. This fellowship provides twelve hundred dollars a year, and may be taken in the medical, neurological, tuberculosis, or cancer divisions of the hospital. Appointments are for one year, and applications should be sent to the Medical Director.

Study of Cerebral Physiology.—Two years' research in cerebral physiology will be undertaken by the Iowa State University, under direction of Dr. Samuel T. Orton, director of the State Psychopathic Hospital and head of the department of psychiatry of the University. The funds will be furnished by the Rockefeller Foundation. A field unit will hold psychiatric clinics in small communities, and a well trained personnel will conduct the laboratory research.

Public Health Nursing.—The University of Montreal has established a school for public health nurses to meet the need in the Province of Quebec for French speaking nurses trained in public health.

Charcot Prize.—A triennial prize of four thousand francs has been established with the surplus funds from the Charcot centennial of last year. This will be awarded by the Société de Neurologie of Paris to a beneficiary it will select and to whom it will assign a topic for research.

Tinkham Scholarships.—One or more scholarships at the University of Vermont School of Medicine are provided for in the will of the late Dr. Henry Crain, dean of the school of medicine. His medical library was given to the college, and his surgical instruments to the Mary Fletcher Hospital.

Study of Maternity Homes.—The Division of Maternity, Infancy and Child Hygiene of the New York State Department of Health, is planning a survey of unincorporated maternity homes in the States. The law provides that all institutions for maternity care shall be licensed by the local board of health; and it is estimated that of the 145 institutions in the state, at least fifty are operating without a license.

Cosmetic Regulations.—Interesting regulations are in force in Italy, regarding cosmetics, dyes, and other preparations for the skin. The name of the manufacturer or seller must appear on the package, and if poisonous substances are part of the preparation, the exact nature of the contents must be printed on the label, and a yellow band attached with information printed on it regarding possible injury from use of the preparation.

Graduate Study of Tuberculosis.—A course in the study of pulmonary tuberculosis and respiratory disorders will be given from October 8th to 23d, at Strasbourg, France, by the Association Alsacienne et Lorraine contre la Tuberculose, in cooperation with the faculty of the University. There will be lectures, presentation of cases, radiological and bacterial demonstrations. Applications should be made to Dr. E. Vaucher, in charge of the course.

Tuberculosis Hospital Admissions.—An admission bureau for all public patients to tuberculosis hospitals and sanatoria, has been arranged by Dr. Louis I. Harris, Commissioner of Health, and Dr. Bird S. Coler, Commissioner of Public Welfare. This will simplify the admission procedures, the Department of Public Welfare conducting the investigations into the economic conditions of the patients and the Department of Health determining the medical requirements of the cases.

Special Course in Stomatology for Dentists and Physicians.—The American Stomatological Association in cooperation with the faculty of the Post-Graduate Medical School of Stomatology at New York City announce a special course of ten lectures for graduates in dentistry and medicine in Stomatology and Focal Infection to begin October, 1926. The classes will be limited in number and students will be registered in the order in which their applications are received. For information, address the Registrar, Post-Graduate Medical School of Stomatology, 135 Elliot Place, New York City.

Gifts and Bequests.—By the will of the late John G. Carruth, the Episcopal Hospital in Philadelphia received $10,000; the Homeopathic and Presbyterian Hospitals each received $5,000.

A bequest of $1,000 was received by the New York Orthopedic Hospital by the will of the late Mary L. Willard.

The New York City Cancer Institute has received $10,000 by the will of Mrs. Annie Lendrock.

The late Mrs. Hannah Heyman, of New York, bequeathed $50,000 each to the Montefiore Home, the Hebrew Orphan Asylum and the New York Guild for Jewish Blind, and $25,000 to the Home for Aged and Infirm Hebrews.

By the will of the late Amanda J. Leslie the Home for Incurables, Philadelphia, the Blind Asylum and the Friends' Hospital received $32,000.

One thousand dollars was bequeathed to the Montefiore Hospital, New York, by the late Supreme Court Justice, David Leventritt.

Personal.—Dr. Aaron Scott Maclaire has been appointed adjunct professor of neurosurgery at the New York Polyclinic Hospital and Medical School, a promotion from instructor.

Dr. Melville D. Dickinson, of Troy, N. Y., has been appointed a district state health officer in the New York State Department of Health.

Dr. J. Arthur Buchanan, of Brooklyn, has moved his office to 510 Ocean Avenue.

Dr. J. Lewis Amster has been appointed attending surgeon to the Jewish Memorial Hospital and consulting surgeon to the Bronx Eye and Ear Infirmary.

Dr. Simon Flexner, director of the Rockefeller Institute for Medical Research, has been made an honorary member of the Microbiological Society of Leningrad, Russia.

Dr. Charles C. Hedges, in charge of public health work for Marshall County, West Virginia, has been appointed second assistant director of the Johns Hopkins Hospital, Baltimore, to have charge of the dispensaries.

Dr. Stanley E. Dorst, of Cleveland, Ohio, has been appointed assistant professor of internal medicine at the college of medicine of the University of Cincinnati.

Dr. Robert Müller, of New York, chief of the Zander Medicomechanic Institute of Carlsbad, has sailed for that institution, to practice during the season. He will return to New York in the fall.

Dr. Benjamin Lipshutz has been appointed attending surgeon of the Mount Sinai Hospital of Philadelphia.

Dr. Clarence L. Scamman, deputy superintendent of health of Providence, R. I., has resigned to take a position as deputy commissioner of health and director of the division of communicable diseases of Massachusetts.

Dr. and Mrs. William C. Mitchell, of Philadelphia, have recently celebrated their fiftieth wedding anniversary.

Dr. H. I. Spector, tuberculosis controller of St. Louis, has resigned to engage in private practice.

Professor Selskar M. Gunn, of the Rockefeller Foundation in Paris, has recently arrived in New York.

Society News and Notes.

Dr. Alfred J. Asgis, general secretary of the American Stomatological Association, spoke before the graduate students of New York University, April 17th, on Biological Foundations of Dental Hygiene.

Among April meetings to be held at the New York Academy of Medicine are the following: the Section of Obstetrics and Gynecology, on Tuesday evening, April 27th, at 8:30, with reports of cases by Dr. Julius Kurzrock, Dr. Henry C. Falk, and Dr. Thomas H. Cherry; papers by Dr. E. G. Langrock on Treatment of Abortion; Dr. George L. Brodhead on Treatment of Placenta Previa with a Report of 165 Cases; and Dr. Leandro Tomarkin on Clinical Experimentation in Sepsis and Pyelitis with Antimicrobin; the Section of Laryngology and Rhinology on the evening of April 28th at 8:30, with a program by the Department of Otolaryngology of the Lenox Hill Hospital; and the Section of Historical and Cultural Medicine on Thursday evening, April 29th, at 8:30, with papers by Prof. Herbert R. Cross, of New York University, on the Historical Orientation of the Art and Time of Akhnaton (Amenhotep IV, 1375-58 B.C.), with lantern slides; and a Psychohistorical Study of Akhnaton, Father in Law of Tutankh-amen, First Idealist and Originator of a Monotheistic Religion, by Dr. L. Pierce Clark.

The seventh lecture of the Harvey Society series was given at the New York Academy of Medicine on the evening of April 17th by Dr. B. Brouwer, professor of neurology at the University of Amsterdam. His subject was Comparative Anatomy and Nerve Pathology.

* * *

The Advisory Commission on Child Welfare of the League of Nations has recently initiated a move-

ment to protect children throughout the world from undesirable moving pictures by adopting a resolution to create central censorship boards in each country composed of educationalists and parents. The resolution stipulates that these boards shall prohibit the presentation of films demoralizing to the mentality and morality of children, and encourage films which are educational in nature. It also recommends an international entente between the national boards with a view to international interdiction of improper pictures, and national legislation to insure proper hygiene and ventilation of moving picture theatres, with ample exits and prohibition of inflammable films.

The Baltimore Medical Club, of New York, consisting of physicians practising in New York City, Brooklyn, and other neighboring cities, who were graduated from the medical colleges of Baltimore, will celebrate its Spring Meeting by a banquet at the Hotel Commodore, on April 29, 1926. Dr. Arthur M. Shipley, professor of surgery at the University of Maryland, will be the guest of honor, and make the address of the evening. Other entertainment will be provided. Dr. James M. Hitzrot is president of the society; Dr. David E. Hoag, vice-president; Dr. William B. Pritchard, chairman of the executive committee; Dr. Leslie E. Gager, secretary, and Dr. L. Winfield Kohn, chairman of the entertainment committee. Tickets for the dinner may be obtained from Dr. L. Winfield Kohn, 427 Park Ave., New York City.

* * *

The Women's Foundation for Health, New York City, is giving a series of health talks over the radio. How to Be Popular is the title of one reprinted in the *Mental Hygiene Bulletin* for February. The speaker broadcasting was Dr. Anne T. Bingham, at that time psychiatrist of the Girls' Service League of America.

* * *

At the thirteenth annual convention of the New Jersey Mosquito Extermination Association recently held at Atlantic City, it was announced that for an annual expenditure of $200,000 on mosquito extermination work, the state of New Jersey has received $43,000,000 in increased taxable values.

* * *

The International Birth Control Organization has announced a conference on birth control to take place August 25th-27th in Geneva prior to the seventh assembly of the League of Nations. It is planned to set up within the international organization an all year round bureau to serve as a liaison centre for the birth control movements in the various countries. Among prominent American scientists who will participate in the conference are Dr. Raymond Pearl and Dr. Edward M. East. Among members of the International Conference are H. G. Wells, Lytton Strachey, Julian Huxley, Dr. Wesley C. Mitchell,, Havelock Ellis, Dr. and Mrs. Frederick Peterson, Sir W. Arbuthnot Lane, and John Maynard Keynes.

* * *

At the annual luncheon held recently in New York City of the Vocational Service for Juniors, it was announced by Dr. Mary H. S. Hayes that 10,285 applicants for positions had been received. Of these fifty-eight per cent. were placed, and each one followed up. Dr. Joseph Jastrow, professor of psychology at the University of Wisconsin, spoke at the luncheon on Personality and the Wisdom of the Moderns. "Students go to college," he said, "not to be educated, but to learn to direct motive and acquire personality. You cannot run an adult well on child motives, and yet we have been trying to do it."

* * *

Dr. Auregan, of Lannion, France, recently outlined before a meeting of the French Dermatological Society his discovery of a remedy for lupus. This remedy consists of a deep curettage of the affected parts followed by a thick application of powdered permanganate of potassium completely covering the diseased areas. Dr. Auregan reported that a single application has always proved to be an effective cure. He said that his successful use of the treatment had covered several years and included many patients, none of whom he was required to see more than three times after the application of the remedy.

* * *

The National Committee for Mental Hygiene has announced its comprehensive program to be given at the American Health Congress at Atlantic City, May 17th-22d. The sessions will be for the most part of the round table type, selected because this seems best adapted to meet the needs of informal discussion, opportunity for which is frequently prohibited by the reading of formal papers. The general subjects chosen are the backward child, the problem child, problems of adolescence, and community and organization problems. Leaders of the discussions will be Dr. Howard W. Potter, Dr. H. C. Schumacher, Dr. Frankwood E. Williams, Dr. Douglas A. Thom, Dr. George K. Pratt, Dr. Charles Bernstein, Dr. Ralph P. Truitt, Dr. George L. Wallace, Dr. Marion E. Kenworthy, Dr. Frederick H. Allen, Dr. Arthur H. Ruggles, Dr. Christine M. Leonard, Dr. Lawson G. Lowrey, Dr. Sanger Brown, 2nd, Stanley P. Davies, Ph.D., and Jessie Taft, Ph.D. On May 20th and 21st there will be conferences of medical directors, executive secretaries, and other persons interested in organization, promotion, financing, educational campaigns, and similar projects in connection with state mental hygiene societies. These conferences will be informal and will provide an opportunity for an exchange of ideas.

* * *

The American Child Health Association has announced that May 1st will be observed as "no accident day" for children. New York City will lead the country in the project. The whole police force has been pledged to cooperate, and Dr. Harris, commissioner of health, has called upon the Department of Education to warn children and their parents about traffic dangers. In Chicago the Boy Scouts, Camp Fire Girls, and similar organizations will aid the police in accident prevention. At midnight a telegrgaphic roll call of cities participating will be held by the Child Health Association to determine which city has been the safest for children during the day.

The project for the creation of a federation of states to succor the victims of disasters was approved in principle by the League of Nations in 1922 and

1923, but assumed definite shape only after the fourth assembly of that body, which decided to submit it to the governments of its member states. Most of these approved, and the same referendum was sent to national Red Cross societies. After having studied the replies, the fifth assembly of the League of Nations decided to consider the project as adopted in principle, with revisions. A preparatory commission has drawn up statutes which were adopted in the main at the sixth assembly. The foundation of this International Relief Union will constitute an important step forward in international understanding, for under such a scheme no disagreements due to race, politics, religion or economic causes are to be feared.

Letters to the Editor.

ATTENTION LAYMAN!

NEW YORK, *April 7, 1926.*

To the Editor:

A little group of us were discussing matters in general at a recent dinner of the Bellevue Alumni Society when the question of fee splitting came up incidentally.

One of our friends quoted an occasion when the same subject happened to be discussed in a group of business men none of whom expressed disapproval of the payment of commissions. They did not understand why a practice common enough among business men should not be legitimate among doctors provided that "the right sort of goods were delivered." Right there is where the joker is played for an ace in the game.

When I first entered the profession fee splitting was unheard of, although it was rumored that some of the eye specialists were careless enough to accept commissions from manufacturers of glasses. There was plenty of disagreement among leaders of the profession on all sorts of subjects. If they united on any one idea, however, it was with the feeling that anything savoring of commercialism in the profession was taboo.

It is quite true that expert specialists in those days frequently failed to get their just desserts in the way of fees. The chief reason for this was that the general practitioner, keenly interested in every single feature of the welfare of his patient, extended this spirit into his consultation with specialists. He would say to one of his patients, for example, "Now you must have a surgical operation performed. I am very well acquainted personally with expert surgeons and I will ask one of them to do this work for you without making much of a charge." Over and over again I have known of physicians saying this sort of thing to people of large means. With the advent of the doctor who would divide fees there came an elevation of the subject into a different atmosphere but we would not call it elevation of the profession. It was a higher but colder atmosphere. A general practitioner who happened to be shameless no longer protected his patient. On the other hand he took him to someone who would charge a large enough fee to make the division something worth while. Good advice and wise counsel were relegated to minor position and fee was moved up to first position. Where is the layman who will fail to see this very blunt point?

I would not by any means imply that experts who now receive large compensation justly and properly for superior quality of work are to be classified among the raptores who look upon the ill man as prey. Dignified men of high standards who maintain the ideals of the profession are quite willing that superior skill should have a superior degree of compensation in medicine quite as much as in other professions. On the other hand the layman who allows a fee splitter to guide his destinies within the ranks of the profession is dealing with a man who is fundamentally untrustworthy and who needs watching; he belongs to the low caste group.

In all the liberal professions we find a nobility group and an expediency group. Each man knowing in his heart to which group he belongs acts accordingly in social relations. The matter was recently put very nicely to a young doctor, already notable, who went to the old physician of his family and said that he was in something of a quandary and did not really know whether to divide the fees or not. The inherent gentility of the old friend of the family allowed of no hiatus between question and answer. He said in effect "your parents are extremely proud of your accomplishments to date. Would they like to look forward to the time when your work is done to the epitaph 'fee splitter' on your tombstone?"

ROBERT T. MORRIS.

PERIODICITY OF PEPTIC ULCER SYMPTOMS

NEW YORK, *November 4, 1925.*

To the Editor:

Much has been said and written about the periodicity of the symptoms of peptic ulcer. Many explanations have been offered for this phenomenon but none seems completely satisfactory.

In the first place, I believe that this periodicity is not at all as frequent as is commonly supposed. In the early stages of this disease there do occur sometimes, but by no means always, remissions at greater or lesser intervals and of variable duration; in the more advanced stages the symptoms are well nigh continuous.

For the remissions there is, I believe, a very simple explanation. When the symptoms of pain, heartburn, etc., are at all severe, the patient naturally will cease eating those foods which, as experience teaches him, cause an aggravation of his symptoms. On account of the pain he will curtail his activities in both business and pleasure. He will rest more than usual. As a consequence, his symptoms will abate. He will continue this regimen until the memory of his pains gradually fades from his mind and he gradually resumes his former activities and yields to the allurements of the "hot dog" and the enticement of chop suey. After a while his symptoms will return and he starts round his circle again.

This, I believe, explains the periodicity in the symptoms of peptic ulcer.

MARKS S. SHAINE.

Book Reviews

CARDIOLOGY

Clinical Disorders of the Heart Beat. By Sir Thomas Lewis, C.B.E., F.R.S. London: Shaw & Sons, Ltd., 1926.

The appearance of the sixth edition of this well known classic on the cardiac irregularities attests to its value and to its popularity. In it are presented the methods of clinical diagnosis, prognosis and the elements of treatment of sinus arrythmia, heart block, extrasystoles, paroxysmal tachycardia, auricular fibrillation and flutter, and alternation. Special emphasis is laid on the use of the unaided senses in the recognition of the irregularities of the heart, graphic records being used merely as illustrations. For students and practitioners there is no better book on this subject. Many selfstyled cardiologists might well take to heart the following statement of this master of graphic methods. "There are few important disorders of the heart beat which the practised senses may not recognize unaided."

CLINICAL STUDIES

Clinique Médicale de L'Hôpital Beaujon. By Ch. Achard, Professeur de Clinique Médicale a la Faculté de Médecine de Paris, Membre de l'Académie de Médecine. Paris: Masson et Cie, 1925.

The second series of Achard's clinical studies contains a number of unusually interesting lectures in his clear and finished style. They deal not only with diagnosis and treatment but with pathogenesis and questions of blood chemistry, as well. Among the reports worthy of special mention we note a case of Morvan's disease. There are excellent chapters on gout, diabetic gangrene, the symptoms, pathology and treatment of diabetic coma, alcoholic paralysis, syringomyelia, Laënnec's hepatic cirrhosis, salt free diet in the treatment of cirrhotic ascites, bichloride poisoning, lead nephritis, and uremia.

X RAY

Röntgenbehandlung Innerer Krankheiten. Von Prof. Dr. W. Parrisius, Privatdozent an der Med. Univ.-Klinik, Tübingen. Mit vierundfünfzig Abbildungen. Leipzig: Verlag von S. Hirzel, 1926. Pp. vii-227.

This handbook, dealing with röntgenotherapy in internal medicine, is intended as a companion book to Jüngling's volume on the röntgenotherapy of surgical diseases. Since the end of the World War, the author has conducted the röntgenotherapeutic department of the Medical Clinic at Tübingen, and he has made it his task to write a book in which the wheat is separated from the chaff in this field of medicine. An outline is given of the physical basis of röntgenotherapy, as the author has found that the röntgenotherapist usually does not know enough about it to give the patient the utmost benefit of the treatment, to which he is entitled. Just enough is included to enable one to use the x ray apparatus intelligently. The physicotechnical part forms the first section of the book. It is couched in simple language and is very valuable.

The second section is devoted to the clinical aspect of the subject, and gives the biological principles and clinical results based on the literature and a critical study of his own results. Except in the cases of leucemia and exophthalmic goitre, about which the literature is too extensive to mention, the bibliography is given very completely. Some of the author's own views are given in certain cases, as in the value of röntgenotherapy in pulmonary tuberculosis and exophthalmic goitre, as these are still moot questions.

The subjects discussed in the second section are the effect of x rays upon the hematopoietic organs, radiotherapy of blood diseases, of tuberculous diseases, of bronchitis and bronchial asthma, of endocrine disorders, and of nervous diseases. The final chapter includes the radiotherapy of miscellaneous conditions and diseases, such as prostatic hypertrophy, arthritides, gastric ulcer, heart disease, nephritis and anuria, liver diseases, tonsillar hypertrophy, and x ray intoxication.

On the whole, the book is up to date and well written. It ought to be of great value to every one who is interested in the subject of röntgenotherapy.

CANCER

Das Krebsproblem. Rückblicke und Ausblicke, Grund- und Scheinprobleme der Krebsforschung, Behandlung und Verhutung. Klinisch-Biologisch Darlegungen. Von Dr. Alfred Greil, Innsbruck. Leipzig: Verlag von Johann Ambrosius Barth, 1925. Pp. viii-181.

The pathologist recognizes that he has reached the limits of the objective demonstration powers of the microscope and the experiment; the clinician and surgeon have reached the utmost possibilities of local surgical therapy. Both now must admit that cancer cannot be cured by the methods followed heretofore. The clinician and pathologist can now only ask the questions which the pathological physiologist must eventually answer. Only the resource to heredity, the systematic investigation of the manner in which embryologic and ontogenetic differences, all disparity of growth, all specification of the constantly correlated differentiation of structure and function out of the condition of absolute indifference, of true uniformity of absolutely similar cells of the mother tissue, are and were acquired; the discovery of changes in condition, through which this epigenetic occurrence can be changed pathologically, can bring the explanation and solution of the cancer problem. Without an insight into the regularities of the dynamics of development, variation and heredity, without the application of Lamarck's and Goethe's, Darwin's and Häckel's, Bär's and Schleiden's recognized general principles of change of form in the germinating and free life, neither the origin of tumors, nor the heredity of the predisposition to such variation, nor the neoplastic diathesis, can be learned and prevented.

The author asserts that we know and suspect that the problem of cancer is only a special case of the causation, treatment and prevention of pathological, endogenic variations in children of healthy parents, of individual children of the same parents, that the acquisition of the first born of such idiopathic conditions proceeds definitely not before or through the impregnation, but most certainly metagam prenatally; that the cancer is rooted not in the germinal cell but in the maternal tissues, and that it can be prevented only by the preservation of the proper development and effective condition of the placental

inoculative growth. Pregnancy is always the most serious constitutional test of the woman.

The cancer investigations of the last twenty-five years and the treatment of cancer during the last thirty years, respectively, are criticized and evaluated. According to the author, the main problem in the investigation of cancer is the application of Darwinism. The pseudoproblems of cancer are refuted. A long and separate chapter is devoted to the future of the investigations of neoplasms as a working program and a reply to Dürck's criticism of the "naturalist's method of the investigation of cancer." The theory and future of the treatment of cancer, the *therapia sterilisans magna combinata,* is discussed in detail. The final chapter deals with the nature and origin, the heredity and prevention of the neoplastic diathesis, and of the general and local predisposition, and also the hygiene of cancer.

The author presents a novel and hitherto neglected aspect of cancer in a philosophic manner. In view of the recent work of Gye on the parasitic theory, his absolute rejection of this theory of cancer is interesting.

HIGH FREQUENCY CURRENTS IN OTORHINOLARYNGOLOGY

La Haute Fréquence en Otorhinolaryngologie. (Diathermy, High Tension, Effluvium, Diathermocoagulation, Surgical Etincelage.) Par Leroux-Robert. Preface du Professeur D'Arsonval. Avec 74 Figures. Médicine et Chirurgie Pratiques. Paris: Masson et Cie, 1925. Pp. 166.

The use of the high frequency current in otorhinolaryngology by Leroux-Robert is entirely new. This current is the result of d'Arsonval's work, and is one of the most important discoveries in physiotherapy. In otolaryngology it finds indications for all its forms. It is an aid to medical treatment because it operates on a highly nervous and extremely vascular sensorial sector, but above all because it is connected with the sympathetic and endocrine systems; it is an aid to surgical treatment because it spreads over an uneven territory, containing outlets, either narrow or difficult of access, and closed cavities.

In the domain of medicine, Leroux-Robert gives the result of his research work for seven years in the use of diathermy in chronic laryngitis, Eustachian catarrh, and exudative otitis, and high tension in eczema, rhinorrhea, headache of sinus origin, tonsillar or laryngeal pains, spasms of the esophagus, otosclerosis, tingling in the ears, giddiness, ozena, and other conditions.

The author reminds us that the use of diathermocoagulation was introduced into rhinolaryngology in 1912 by Bourgeois and Poyet. Besides his personal observations, he sums up synthetically the work of his predecessors in the treatment of hypertrophy of the tonsil, papilloma, angioma, hemorrhagic fibroma of the nasopharynx, atresia, strictures, adhesion between the palate and the pharyngeal wall.

Surgical etincelage having not yet attracted attention, he draws a parallel between the results of this method and those of diathermocoagulation with regard to the treatment of mild tumors, cancer, tuberculosis and lupus.

Leroux-Robert appeals both to specialists in rhinolaryngology and to those general practitioners who are interested in the results of high frequency.

By an arrangement of the text enabling instant information on any point, an abundance of diagrams and plates, and a synoptic plan, this book becomes an extremely objective document. It is accompanied by photographs which give a vivid impression of the actual demonstration.

Professor d'Arsonval, who has inspired by his genius all research work on the medical high frequency current, has written the preface.

The book should prove of great value, not only to the specialist in diseases of the ear, nose, and throat, but also to the general practitioner.

TUMORS OF THE EYE

Die Bösartigen Geschwülste des Auges. Von H. Sattler. Mit 25 Abbildungen im Text und 9 Tafeln. Leipzig: Hirzel, 1926.

In this volume the well known Leipzig ophthalmologist has been able to add many details to his study of the malignant neoplasms of the eye, originally appearing as a special chapter in the *Zweifel-Payr Klinik der Bösartigen Geschwülste.* This applies particularly to the pathologicoanatomical aspect. Sattler notes with regret the frequency with which malignant tumors of the eye escape early detection or correct diagnosis, so that treatment is not instituted in time to be of real value. Accordingly he is at pains to lay special stress on clinical and ophthalmoscopic features which make an early diagnosis possible.

The illustrations, almost all of which are by the author, deserve more than a passing word, not only for their technical excellence and artistic beauty but for their didactic value. This applies to the drawings of the photomicrographs of sections, as well as to the color drawings of the fundus, particularly. The early stages of various intraocular growths are most instructively shown.

Sattler's volume deals not only with tumors of the optic nerve and retina, sarcoma of the choroid and iris, glioma of the retina, but with epibulbar sarcoma, naevus carcinoma, and malignant growths of the cornea, conjunctiva, and lids.

CELLULAR IMMUNITY

Die zelluläre Immunität in ihrer Einwirkung auf Entstchung und Behandlung von Konstitutions—und Infektionskrankheiten. Von Hofrat Dr. med. Adolf Theilhaber, München. Berlin: C. F. Pilger & Co., Medizinischer Verlag. Pp. 38.

This brochure contains the main lectures held by Theilhaber at the All Russian Gynecological Congress at Moscow in 1924.

It deals almost exclusively with cellular immunity and with its relationship to constitution, cancer, tuberculosis, atheromatosis, chronic arthritides, postoperative wound infections, and syphilis. The most important section is the one dealing with the "reinforcement of cellular immunity." In contrast to other investigators, the author attaches greater importance to the cellular, the nonspecific, the local and to the active immunity than to the blood and the specific immunity. All cells and all body fluids must contain protective arrangements against noxa. He recommends the stimulation of the activity of the lymphocytes (emulsion of spleen upon ulcerated carcinomas), the injection of proteins (of lymphocyte substance), diathermy, and other stimulants that result in a stimulation of the cellular immunity. The

author ascribes a special value to nonspecific cellular immunity in the prophylaxis of disease. The dissemination of cancerous diseases in all civilized countries assists the deficient cellular immunity. The diminished powers of resistance to excitants of disease should be attributed to an insufficient intake of mineral salts and to the increased consumption of meat and alcohol and to the use of nicotine.

MEDICAL ANNUAL

The International Medical Annual. A Year Book of Treatment and Practitioner's Index, 1925 (Forty-third Year). New York: William Wood and Company, 1925.

The issue of the *Medical Annual* under review has been prepared along the general lines laid down in the past, which have met with widespread approval.

Twenty-eight contributors, among them several of the best known English physicians and surgeons, are represented in this most useful volume. Not a few of the names among this list are well known in the United States.

The editors have prefaced the main work by an introduction which aims to set forth those advances of the past year which seem likely to become part of the permanent medical equipment. A few of the subjects thus considered are the injection of foreign protein in migraine, epilepsy and asthma; inoculation with malaria in general paralysis; the insulin treatment for diabetes; the treatment of chronic ulcerative endocarditis by injections of sodium cacodylate; a note on coeliac disease of early childhood and the effects of the administration of chlorides in the tetany of childhood. The work is crowded with most valuable medical data, covering every branch of medicine and surgery. It is surprising that so much material has been included within the covers of one handy volume and both the editors and publishers are to be congratulated on the result. This is a work which can be commended to the general practitioner with little time for wading through verbose textbooks.

AMERICA AND GERMANY

America and Germany, 1918-1925. By Sidney Brooks, Author of *America and Poland, 1915-1925* and *Russian Railroads in the National Crisis.* With a Preface by George Barr Baker. New York: The Macmillan Company, 1925. Pp. xviii-191.

This is "the record of intimate relations between the representatives of two nations connecting events the significance of which is brought out for the first time." It is the story of the help offered by America to Germany in the way of feeding the German population, giving at the same time a keen insight into the postwar feelings and public opinion of the conquered people. The problems of shipping and finance, upon which the success of the undertaking depended, are discussed. There was also the difficulty of Germany's internal dissension to be considered. This was aggravated by the hostility of the Allied nations, especially France. America felt the need of stepping into the breach.

The work of such men as Hoover, Dawes, the American Relief Administration, the Quaker feeding of children, etc., are all given ample consideration. The original correspondence on various subjects is reproduced.

The spirit of the American people toward Germany is best expressed in Hoover's words: "There is a country of sixty million people with whom the world has to live and whose economic cooperation is necessary to give life to the rest of the world. There is no other task open except to try to live and cooperate wholeheartedly with them." This has been accomplished. It is a wonderful story—an epic.

Medicoliterary Notes.

The *Porto Rico Health Review* is the title of the new monthly official bulletin of the Department of Health of Porto Rico, which began publication recently.

* * *

The Scottish Board of Control in its recently issued annual report states that there was a substantial increase during the year in the number of voluntary inmates of institutions for the insane and the mentally defective. A scheme is under way for building colonies for adult defectives which will reduce to a minimum the practice of committing such persons to institutions for the insane.

* * *

A new word has been made popular in America by the U. S. Weather Bureau. It is *smog,* which prevails when smoke and fog unite at the same density, the smoke particles crystallizing in chilly air and being carried along in a fog blanket. New Yorkers are in a position this winter to testify heartily to a knowledge and experience of smog.

* * *

There were 169,723 accidents in British factories and workshops in 1924, 956 of which were fatal, says the *Economic World.* The increase over 1923 of 44,162 accidents is considered as due to increase of reportable accidents under the new laws shortening the period of notification. By far the greatest proportion of accidents occurred in a limited group of industries. Shipbuilding and other building trades led in fatal casualties.

* * *

An analysis of five hundred conversations overheard in Columbus, Ohio, on the street at games, and in theatre lobbies, barber shops, and churches, is reported in the *Journal of Comparative Psychology.* Men's most frequent conversational topics were: Business, forty per cent.; sports and amusements, fifteen per cent.; talk about other men, among themselves, twelve per cent. The leading topic of women's conversation was men—twenty-two per cent.; clothes came in for nineteen per cent., and, among themselves, about other women, fifteen per cent.

* * *

The student yearbook of the senior class of Johns Hopkins University has recently issued to members of the class a list of twelve vices, which they are asked to arrange in the order of their seriousness, as an indication of the varying codes of morals of student groups. The vices are lying, cheating, gambling, stealing, sex irregularity, selfishness, snobbishness, vulgar speech, drinking, laziness, extravagance, and dancing. Another list of very personal questions was also sent out.

* * *

We noted the other day the fact that Professor Bergson had fourteen doctors in connection with his ailment. Bismarck ran through twenty-nine before he at last came to Professor Schwenninger, who succeeded in reducing his fat. Even then the result was not achieved without much personal friction. Schwenninger, his first interview, pestered his patient, the Iron Chancellor, with so many questions as to his habits of life that at last the prince lost his patience and said, "You ask me too many questions."

"Very well," said Schwenninger, "you go to a veterinary surgeon, as he won't ask you any."—*London Evening Standard.*

* * *

In Flikeid v. New York Life Ins. Co. (Minn.) 203 N. W. 598, it conclusively appeared that the insured, prior to his application for the policies on which suit was brought, had consulted and was treated by a physician, which facts he denied in the application, that this materially affected the

risk, and that the risk would not have been accepted had the truth been revealed. Judgments for plaintiffs were reversed and directed to be entered for defendant.

* * *

At a lecture recently given before the students of Cambridge University, England, by Kenneth Bell of Oxford, on the subject of preparation for their careers, the following "don'ts" were included: Don't have European wars in the middle thirties; Don't get engaged to be married in your first year at the University; Don't get married at twenty-four; Don't have six children; Don't get into an old established family business. "It is impossible," he is quoted as saying by the *New York Times*, "to have a successful future without the spice of hate. This is essential in order that you may react against your environment. . . . If you have a big mental test, it is not sensible to knock off tobacco."

* * *

An interesting article on the relationships between the origin of odors, the creation of colors, and the phenomena connected with light, heat, magnetism and electricity is contained in the current issue of the *Perfumery and Essential Oil Record*. The writer is A. C. Hopper who has been for a long time engaged in investigating the subject of odors and their causation. His work is based on the theory that the phenomena of odors, like those of light, are wavelike radiations, possibly "odorant ions" which are freed as unsatisfied electrical charges in the collision of atoms in strongly odorous substances.

* * *

The American taste for edible snails has increased so rapidly since the war the supply imported from France is now by no means adequate to fill the demand. Hence French snail raisers are using artificial rain and sunlight to produce a winter supply of *escargots au bibron* (milk bottle snails) equal in quantity to that of the summer months. This is done by covering the floors of cellars with mulberry leaves and sewing among them thousands of baby snails. Since snails always eat immediately after a shower followed by sunshine, the growers turn the hose on the mulberry leaves, then turn on strong electric lights. Thus the snails are "fooled" into thinking that summer has come, and stick their heads out of their shells. Then they are sprayed with a mixture of milk and flour from large jugs, of which they partake and grow to be best milk bottle snails for our consumption.

* * *

Dr. S. Monckton Copeman, lecturer on hygiene and public health at the Westminster Hospital School, London, has an interesting article in the *Pharmaceutical Journal and Pharmacist* on tests which he has been making as to the medical and dietary virtues of water cress. He has experimented with both animals and human subjects, and in both cases the results were markedly successful, particularly with the latter. The ages of the human subjects varied widely; in all cases they gained in weight, improved in appetite, their skin became much more healthful, and constipation if it existed was entirely removed. He also studied the cress itself to discover the chemical basis for its dietary virtues; and found that the residue from the extracted juices of the plant gave marked reactions with all the test solutions for alkaloids. A glucose present in the form of potassium salt was first isolated. He found also that water cress contains the three vitamines, A, B and C, together with salts of potash and iron, in addition to a considerable quantity of iodine.

* * *

The influence of the socalled evolution trial of last summer at Dayton, Tennessee, has extended to Moscow, where a play has been produced reproducing almost all the outstanding incidents of the trial. The author of the satire is D. D. Bogomolov, who makes his play revolutionary propaganda, showing, in his opinion, the hopeless disparity between capitalistic doctrines and the socalled pure sciences as represented by communism. The principal actors in the play imitate the appearance, ways, grimaces and voices of various animals. An ape is judge of the court, and other characters include a pig, a baboon, a turkey, dogs, cats, etc.

* * *

Amazing Stories is the title of a new fiction magazine which calls itself a periodical of "scientification." This, an introductory editorial explains, means that the type of story published will always be apparently scientifically plausible, like those of Jules Verne, H. G. Wells, Poe, etc. The April issue contains stories by all these authors, and others by G. Peyton Wertenbaker, George Allen England, and Austin Hall—all real "thrillers" for those who like that kind of tale.

* * *

Interesting articles in the issue of the *Nation's Health* for February include Knowledge of Cancer Increases, by Dr. Francis Carter Wood, and Good Seating Lessens Fatigue and Increases Output.

* * *

The U. S. Children's Bureau has recently issued as Publication No. 148 a legal report on Adoption Laws in the United States, compiled by Emelyn Foster Peck.

* * *

How Can the Chances of Curing Cancer Be Increased? is the title of an article in the February issue of the *World's Health* by Prof. G. Winter, former director of the Clinic for Women's Diseases, Koenigsberg, Prussia.

* * *

British radio regulations require that all radio talks on public health may be broadcast only by physicians whose lectures have been approved by the General Medical Council. Neglect to apply for official permission to broadcast renders the physician liable to a charge of advertising for the purpose of securing patients.

* * *

Public Health Reports for February 12th contains a report from state health officers of thirty-eight states for eleven months of 1925, compared with the same period in 1923 and 1924. The total number of cases was as follows: 1923 had 21,233 cases; 1924 had 43,029 cases; 1925 had 31,037 cases. The increase in 1924 amounted to one hundred and three per cent.; the decrease in 1925 was twenty-eight per cent. The figures for 1925 are forty-six per cent. higher than those for 1923. This is rather bitter evidence that we have been boasting perhaps too confidently of the conquest of modern medical science over epidemic diseases.

* * *

The U. S. Department of Agriculture has issued as Miscellaneous Circular No. 49 a useful little pamphlet entitled a *Guide to Good Meals for the Junior Homemaker*. The information contained includes the five food groups and their characteristics, calories, planning meals, weight and height tables for boys and girls, and other useful facts.

* * *

Kipling's jungle was reproduced in miniature recently in Minden, Germany. A sudden flood of the River Wehr cut off a fox, two hares, and seven rabbits on a little island, says a dispatch to the *New York Times*. The water rose until the island was reduced to the top of a pile of beetroots on which the ten animals had scarcely room to turn. From the nearby village people watched, expecting to see hungry Reynard make a meal of one of the rabbits. But, as in the case of the jungle drought, the animals made a truce in the face of danger. For three days and three nights the hungry fox shared his narrow bed with his companions, even though the latter had been able to nibble the beets and did not share his pangs. On the fourth day the peasants shoved out a boat to rescue the marooned beasts, but Reynard preferred death to capture.

* * *

The *Monthly Labor Review* for March contains two valuable contributions to the subject of accident prevention, namely, the special article entitled Progress in Accident Prevention, by Lewis A. De Blois, manager of the safety and compensation division of the E. I. Du Pont de Nemours Company, and former president of the National Safety Council; and the Importance of a Safety Conscience in Accident Prevention, abstracted from an address by John F. Tinsley before a joint meeting of the Industrial Safety School and the Industrial Club of the Providence Safety Council.

* * *

The El Paso County Medical Society is publishing a series of informative articles, in regular paid space, in the papers of that city. Three which recently appeared are: What the Physician Has Done for Humanity, Disease and Its Prevention, and What Does Your Physician Know.

* * *

The Hospital Information Bureau of the United Hospital Fund of New York, with offices in the Academy of Medicine, has prepared a very useful directory of convalescent homes of New York and vicinity. This gives complete information regarding type of patients accepted and other necessary data.

Abstracts from Current Literature

CARDIOVASCULAR DISORDERS

Preoperative Treatment of the Heart with Digitalis.—Erich Meyer and Albert Reinhold (*Klinische Wochenschrift,* October 8, 1925) found that both dogs and men possess an individual susceptibility to digitalis, varying exceedingly. It is a well known fact that serious and protracted cardiac irregularities may lead to circulatory insuffciency even with hearts anatomically absolutely healthy, and therein lies the danger of digitalization before laparotomies.

It is asserted by some that the heart needs strengthening by the prophylactic use of digitalis because of the dangers from the operation or anesthesia, or both. But it is generally admitted that a normal heart cannot be made to act beyond its optimal power, and therefore the prophylactic digitalization has no place in the preoperative treatment in the presence of a normal heart; it may even be dangerous.

Conditions are different, however, when the heart is known to be diseased, in which case a more or less prolonged course of treatment before the operation is frequently necessary. The dose must be arranged individually according to the condition and the manner of reaction. Attention is called to the difficulty of determining the dose in the disturbances of cardiac conduction, which can be favorably influenced by very minute doses of digitalis in combination with atropine and physostigmine. It should be remembered that hypertrophic hearts bear digitalis very well even in the presence of a high blood pressure, and that with overdistention of the right heart with an occasional auricular extrasystole the dose of digitalis should be small, so as to avoid the danger of a resulting auricular flutter. But all of these matters require a preparation of the heart by a cardiologist, and interest the internist more than the surgeon.

Angina Pectoris: Its Mechanism and Treatment.—According to William D. Reid (*Boston Medical and Surgical Journal,* January 28, 1926) the treatment of angina pectoris has for its objectives the relief of the attack and the prevention of the recurrence.

For the attack a rapidly acting vasodilator has been found most useful. Nitroglycerine, in the author's experience, is the most satisfactory drug. It is given preferably in the form of a soft tablet containing 0.006 gm., and allowed to dissolve under the tip of the tongue. By this method it is absorbed directly into certain veins and passes into the general circulation without having to go through the capillary system of the liver; its action should be obtained in about three to five minutes. A second tablet may be given in ten minutes, if needed. In some instances a favorable effect is not achieved unless a much larger dose is used; the administration of the drug should be pushed until the anginal attack is relieved or evidence is obtained of beginning toxic effect. The inhalation of the fumes of amyl nitrite in the form of a "pearl" containing 0.3 c.c. and freshly crushed in a handkerchief, is preferred by some patients. It has been pointed out that in the administration of amyl nitrite the initial fall of the blood pressure is sometimes followed by a temporary rise to a point higher than that obtaining before the use of the drug. Because of the possibility of this sharp rise in the blood pressure some physicians prefer not to employ amyl nitrite in cases of chronic arterial hypertension.

Morphine, 0.01 to 0.015 gm. by subcutaneous injection, works well and has the added benefit of assuring a quiet patient for several hours. In true angina pectoris the use of morphine may well be restricted to this second effect, namely, that of quieting the patient, and for this purpose its oral administration is satisfactory. Many cases may be well handled without the resort to narcotic medication. Where morphine is really needed is in the treatment of continuous pain such as is met in some cases of coronary infarction, in which experience shows that drugs of the vasodilator class are but partially successful.

Heat in the form of an electric pad, or hot water bag, may be applied to the precordium in severe cases, some patients, however, are intolerant to any pressure in that region. The patient ought, ideally, to be kept at rest until one or two days have passed in which no anginal attacks have occurred, as it is known that the paroxysms tend to occur in cycles and the attack may be repeated. The author does not believe anything is gained by keeping these patients in bed for long periods solely because of the angina pectoris, provided the attacks have ceased; prolonged restriction of the elderly to bed is harmful in the loss of muscular strength and the very definite danger of hypostatic pneumonia. As it is only occasionally that the physician is present at the time of the anginal seizure, the patient or a member of the family should be carefully instructed in the treatment of the acute attacks.

Between attacks measures should be taken to prevent their repetition. Success is most likely to be achieved if the therapy is directed along two main channels.

1. Predisposing conditions. These should be detailed to the patient so that, if possible, they may be avoided. Conditions which are prone to be followed by attacks of angina pectoris are: Exertion, especially if sudden, or severe excitement, worry, chilling of the skin such as getting in between cold sheets, walking against a cold wind, sexual intercourse, straining at stool, late suppers, large meals, and flatulency.

2. Treatment of the underlying disease of the heart. To accomplish this therapeutic objective it is necessary to carry the diagnosis to a recognition, wherever possible, of the type of heart affection with which the anginal syndrome is associated.

Surgical Treatment of Mitral Stenosis.—H. S. Souttar (*British Medical Journal,* October 3, 1925) describes, what he believes to be, the first occasion upon which an attempt has been made to reach the mitral valve in the human being, or to subject the interior of the heart to digital examination.

Under intratracheal anesthesia, a curved incision was made along the fourth left intercostal space, up along the middle of the sternum, and outward along the first left intercostal space. The skin and subcutaneous tissues, with the left breast, were turned outward, exposing an area of the chest wall about five inches square. On the outer side of this area a short horizontal incision was made along each of the three ribs exposed, and through these incisions the ribs were in turn divided. The chest wall was now divided a little within the line of the original incision by cutting through the muscles and costal cartilages, and the flap so formed was turned outward, the pleura being included in the flap.

A very full exposure of the left side of the pericardium was thus obtained, while with an intratracheal pressure of 15 mm. Hg there was only moderate collapse of the left lung. The action of the heart then became extremely hurried, but after a wait of five minutes it again became slower and steadier. The pericardium was opened by a vertical incision three inches long, in the centre of which the left auricular appendage came prominently forward. Two sutures were passed through the upper and lower margins of the appendage, so that it could be readily drawn forward. As the heart was still beating very rapidly a subcutaneous injection of one one hundredth grain of strophanthine was given. After a delay of ten minutes, the auricular appendage was drawn forward, a soft curved clamp was applied to its base and it was incised in an anteroposterior direction with scissors. Into this opening the left forefinger was inserted, the clamp withdrawn, and the appendage was drawn over the finger like a glove by means of the sutures. The whole of the inside of the left auricle could now be explored with facility. It was immediately evident from the rush of the blood against the finger that gross regurgitation was taking place. The finger was passed into the ventricle through the orifice of the mitral valve without encountering resistance, and the cusps of the valve could easily be felt and their condition estimated.

The finger was kept in the auricle for perhaps two minutes, and as long as it remained in the auricle it appeared to produce no effect upon the heart beat or the pulse. The moment, however, that it was passed into the orifice of the mitral valve the blood pressure fell to zero, although even then no change in the cardiac rhythm could be detected. With a little manipulation the tip of the appendage was then grasped between the finger and thumb, which held it securely closed while an assistant passed a silk ligature round it and tied it off. The pericardium was closed and a certain amount

of blood, which had escaped into the pleural cavity, was sponged out. The intratracheal pressure was raised so as to cause the left lung to expand, and the wound was closed in layers, the ribs being accurately sutured in position. Immediately the chest was closed the heart's action returned to normal, and on the conclusion of the operation the general condition of the patient was indistinguishable from that at the beginning. The patient made an uneventful recovery.

The value of the operation cannot possibly be judged on a single case, but the author claims to have shown that the method is practicable and reasonably safe. It was intended to divide the aortic cusp by passing a thin hernia bistoury along the finger and thus to relieve the stenosis, and this could have been done with perfect facility had it been considered advisable.

The author believes that the method of digital exploration through the auricular appendage cannot be surpassed for simplicity and directness. Not only is the mitral orifice directly to hand, but the aortic valve itself is almost certainly within reach, through the mitral orifice. Owing to the simplicity of the structures, and, oddly enough, to their constant and regular movement, the information given by the finger is exceedingly clear, and personally the author felt an appreciation of the mechanical reality of stenosis and regurgitation which he never before possessed.

Acute Obstruction of the Coronary Artery.—James B. Herrick (*Northwest Medicine,* December, 1925) says that treatment should be directed toward conserving the heart's strength in every way possible and in prolonging the time of rest until danger from rupture of the heart, acute dilatation, etc., seems well over. Not a few errors have undoubtedly been made in regarding some of these cases as simply gastric upsets and permitting the patient to begin to move about too soon.

Rest in bed should be strictly enforced. The patient should have his choice as to position in bed, sitting up or lying down. Exceptionally he may have to be allowed to spend his days and nights in the chair. Diet should be light and food producing gas should be avoided. Enemata or cathartics should be given to induce easy stools and to avoid straining.

Morphine may be necessary for the pain. At times this has to be repeated and in fairly large doses. Heat to the chest or sinapism are advised by some. Their value is doubtful.

With the feeble, often irregular, heart digitalis should be given. So far as he knows, the author says no case of rupture of the heart or other untoward accident due to the use of digitalis in this condition has been reported. It strengthens the heart action and presumably improves coronary circulation. And it is largely on the establishment of an efficient collateral circulation that hope of recovery rests. Stimulants, such as camphorated oil, caffeine or strychnine, also have a place and should be employed when heart failure seems threatening.

The Neurological Mechanism of Angina Pectoris and Its Relation to Surgical Therapy.—Wilder Penfield (*American Journal of the Medical Sciences,* December 1925) presents the following conclusions from a study of two patients who had been operated on to give relief from angina pectoris.

1. The removal of a sympathetic ganglion removes the possibility of angina pectoris in the motor distribution of that ganglion only.

2. Pain is still possible in the motor distribution of the remaining ganglia, provided the stimulus arising in the heart or aorta is adequate.

3. Success in the operation depends, not upon interrupting a direct afferent path from cardiac plexus to central nervous system as has been assumed, but upon the interruption of autonomic reflexes.

4. Complete cervical upper thoracic sympathectomy abolishes the pain, but should only be employed in cases where life is really insupportable even under the best medical care.

5. Removal of the superior cervical sympathetic ganglion does not render angina in the motor distribution of the other ganglia impossible. Its removal can only be justified on the basis of some resultant alteration in the coronary vessels or aorta which are innervated by it through the superior cardiac nerve.

6. Even if the operation is successful in abolishing pain, the patient should not be called cured but should still be considered as having a serious cardiac disease, and be treated accordingly.

Incidence of Arteriosclerosis in the Arteries of the Body.—D. Rutherford Dow (*British Medical Journal,* July 25, 1925) found that in any one body the distribution of arteriosclerosis was variable. Its presence in one artery was no indication that arteries in other regions would be involved. The arteries in eight bodies were examined.

The abdominal aorta, common iliac, femoral, and popliteal arteries were more frequently and more extensively affected than any other vessels in the body. The internal iliac arteries were more commonly involved than the external iliac arteries.

It was a striking fact that the mesenteric arteries were seldom the seat of degeneration. In one instance only was the inferior mesenteric artery affected.

The parietal vessels in the pelvis, specially the gluteal and pudendal arteries, were affected to a very marked degree. They offered a comparison with the visceral branches in the pelvis, which were seldom involved.

The portion of the internal carotid artery which lay in the cavernous sinus, and the part involving its bifurcation into the anterior and middle cerebral arteries, frequently presented arterial degeneration of a very advanced degree. The vessel wall in this region was usually sacculated. Compare that with the cervical portion of the internal carotid, which was subject to a very small amount of degeneration.

The vessels of the lower limb were more frequently and more extensively affected with arteriosclerosis than those of the upper limb. In one specimen only was the axillary artery markedly involved, and only in one brachial artery was a small patch of degeneration present. A very different condition was found in arteries of approximately the same calibre in the lower limb, where the femoral and popliteal arteries were extensively affected.

The radial arteries (when involved) showed degenerative changes just above the wrist joint, but were not affected higher up.

The tricuspid valve and pulmonary artery were not implicated in any of the speciments examined. They offer a striking comparison with the mitral valve and thoracic aorta, both of which were found to be a frequent site of degeneration.

Liver Disease Caused by Heart Defects.—Harlow Brooks (*Medical Clinics of North America,* September, 1925) states that extensive and serious disease of the liver develops as a result of defective heart action, not only in chronic diseases, but in many acute ones also. It is quite frequently seen in cases of convalescent scarlet fever or pneumonia, after toxic myocarditis or endocarditis in tonsillitis, and especially in convalescence from influenza. Often the heart defect is occult; perhaps because the patient is in bed without being subjected to extraordinary stress, or the heart defects may be obscured by noisy breath sounds, by pericardial effusions, edematous thoracic walls; the elemental defect may be a narrowed coronary, even without the symptoms of angina. Yet in many of these very cases the cardiac defect may manifest itself chiefly or perhaps even solely by liver changes.

In all these cases the basic fault lies in a congestion of the liver due to defective action of the right heart, sometimes valvular (tricuspid disease, notably incompetence). Defective clearance of the right chambers of the heart produces immediately a damming back of the return flow from the inferior vena cava and distention of the hepatic veins and a resulting distention of the intralobular capillaries. Inevitably the pressure on the cells of the distended blood capillaries is followed by atrophy of the liver cells with irreparable damage on the liver cells, possibly death and necrosis, giving rise to brown atrophy, fatty degeneration, with profound alterations in the metabolism. At the same time great and abnormal pressure is exerted also on the bile capillaries, proper drainage is prevented, and, no doubt, proper bile secretion (or excretion?), and jaundice results. As a result of the pressure on the faultily constructed intralobular capillaries hemorrhages take place in the liver substance. The cells break down and blood detritus appears in the extravasated areas. Some of this detritus remains where it appears, some is taken up by leucocytes and fibroblasts, and some is apparently picked up by the liver cells. In either case it acts as a foreign body, and therefore as an irritant. Cell infiltration occurs, fibroblasts appear, and in the end a proliferation of the normally exceedingly delicate connective tissue stroma of the lobule takes place. More atrophy of liver cells, more pressure on bile ducts, more jaundice, and more defective

liver conditions result. If the interlobular connective tissue is thus excited to growth, subsequently to cicatrization, an interlobular cirrhosis occurs.

It is exceedingly difficult to differentiate diagnostically between liver changes caused by primary circulatory discrepancies and those other conditions which lead to the socalled essential diseases of the liver. The liver may be large or small in size, its surface may be smooth or nodular, so very much depends on the individual idiosyncrasy and reaction of the patient, on his age as well as on the duration of the process, and also the subsidiary factors concerned in the case, as gluttony, an indiscreet diet, alcohol, etc. Obviously, about the same may be said of the symptomatology. One of the most serious stumbling blocks in the recognition of liver disease due the cardiac defect is occult heart disease.

The prognosis should always be held in abeyance until the therapeutic test has been made and until we are able to say definitely that the cardiac lesion is or is not a curable one, or if the changes already present in the liver may not under favorable conditions subside.

As to treatment, it is, of course, obvious that the primary essential is to attack the primary defect—the faulty heart. In most cases this can be most essentially encompassed by rest—physical and emotional. The majority of the cases show the most strikingly good results in so far as the heart and liver are concerned, when they are put upon some form of the digitalis group of drugs. Efforts must also be directed to the elimination of all those conditions which may accelerate the liver process, such as the proper limitation of food, according to the needs of the body, the elimination of all hepatic irritants such as alcoholics, the spices and aromatics; the diet should not be too highly nitrogenous. If ascites or edema is present, the fluids and salt must also be restricted. Purgatives should be used discreetly. The salines act best. Some cases show marked benefit from the diuretics, caffeine, sodium benzoate, diuretin, theosin and arsenural. Massage, active and passive movements, may well be applied in some instances, but the cardiac defect and the heart must be watched most carefully. No overload of any kind is to be permitted, and drugs are to be used symptomatically whenever necessary.

The Present Status of the Effect of Organ Extracts on the Control of Blood Pressure.—W. J. Macdonald and T. C. Burnett (*Boston Medical and Surgical Journal,* March 4, 1926) tell us that an extract of the liver has been obtained which possesses the property of reducing to a certain extent essential arterial hypertension, and that it is quite possible that the active principle of this extract may be recovered from other body organs and tissues. This extract contains no protein, no peptone, relatively small quantities of histamine, and relatively large quantities of cholin. It is possible that the effect produced by a proper combination of these two substances may be responsible for the lowering of pressures, but it is more probable that the result is due to an unknown substance, or that this unknown substance may activate the histamine, the cholin, or both. Intramuscular injection is much more efficacious than intravenous. The extract is much more effective in hypertensive than in normal cases. We have as yet no method of selecting cases for treatment, and no method of determining the dose in units in any given case.

Periarteritis Nodosa.—George B. Gruber (*Klinische Wochenschrift,* October 8, 1925) describes the pathology of periarteritis nodosa as follows:

Periarteritis nodosa is a histologically rather sharply characterized inflammatory expression of varying infectious toxic origin, which appears in independent nodes in the mediumsized down to the smallest arterial branches. It is characterized by a warping necrosis in the medial and intimal walls of the arteries as a result of exudative processes, which penetrate from the adventitia and also to a slight extent from the lumen of the bloodvessel, toward the media and intima, and eventually by the formation of granulation tissue in the outer layers of the vessel wall; this granulation tissue, together with the subintimal increase in tissue, which should be considered as a phenomenon of accommodation, leads to the cicatrization of the periarteritic sites. Thrombosis, hemorrhage, rupture and aneurysm, destruction, and infarction in many forms are the results of the nodular inflammation of the arterial wall.

Periarteritis nodosa is not a disease entity, but a peculiar hyperergic expression of arterial wall sites that have become hypersensitive in one or many organic systems in the course of a protracted infectious, or septic disease. It is the most characteristic sign of this disease and is characterized clinically by different and not always existing symptoms as well as by associated symptoms, which have nothing to do immediately with periarteritis nodosa. Nephritis and degenerative neuritis are not infrequently associated with it, and gastric and intestinal symptoms frequently occur with the very beginning of the disease. The ending with the picture of a vascular sclerotic kidney disease is frequently observed and a pallid appearance of the patient is considered as a classical indication of the diagnosis. The duration of the disease varies between one week and several months, and the prognosis is unfavorable in spite of a few cases in which recovery has occurred. The ultimate cause of death is not always the same, and must be sought in marasmus or in anemia, sometimes in acute internal hemorrhage (brain, lungs, stomach, intestine, peritoneum, and kidneys), sometimes in peritonitis, in pulmonary edema, and uremia.

High Blood Pressure.—R. D. Rudolf (*Canadian Medical Association Journal,* November, 1925) says that a rise in arterial blood pressure may be due to nervous, toxic or organic causes. In all cases it is wise to urge a less strenuous physical and mental life, a reduction of diet, especially of the purin containing articles, and the free action of the bowels. Beyond this régime no treatment is required in the absence of symptoms. Where symptoms are present the pressure may be reduced by various measures.

Studies of the Vascular Changes in Cases of Polycythemia Vera.—George E. Brown and Herbert Z. Giffin (*American Journal of Medical Sciences,* February, 1926) studied fourteen cases of this disease with relation to the vascular readjustments to the increased volume of the circulating blood. The total volume of blood was increased in all; the average was 166 c.c. for each kilogram of body weight. The viscosity of the blood was increased in all. The hematocrit values for the cells averaged sixty-two per cent. The capillaries of the nail fold showed venous engorgement in thirteen cases, ninety-two per cent., arterial in four. Engorgement of retinal veins in nine, sixty-four per cent. Engorgement of skin capillaries and retinal veins disappeared when the total volume of blood had diminished to one hundred to 110 c.c. per kilogram. Cardiac enlargement and cardiac disease were noticeably absent. Liver was slightly enlarged in fifty-seven per cent., spleen enlarged in all. There was no increase of blood pressure and the renal function was but slightly impaired.

The Action of Nitrites Upon Pulmonary Circulation. I. Nitroglycerin.—George L. Love and Hugh McGuigan (*Journal of Laboratory and Clinical Medicine,* August, 1925) used dogs for these experiments, the results of which show that nitroglycerin in small doses often produces a rise of pulmonary pressure due to increased cardiac output from acceleration and increased venous return. Nitroglycerin reduces a high pulmonary pressure apparently by dilating the pulmonary arteries. It did not stimulate excised pulmonary arteries. Thus the action of nitroglycerin is the same upon pulmonary and systemic arteries, although less marked upon the pulmonary vessels. The action upon pulmonary pressure is, however, often counterbalanced or overbalanced by the secondary effects of its action upon the systemic vessels. The action of nitroglycerin on pulmonary circulation does not justify its administration in the treatment of pulmonary hemorrhage. Experimentally, at least, it appears to be contraindicated in hemoptysis.

II. Sodium and Amyl Nitrite—George R. Love, Hugh McGuigan, and Charles E. Wiley (*Journal of Laboratory and Clinical Medicine,* August, 1925) found that amyl nitrite and sodium nitrite, particularly the latter, often raise the pulmonary pressure in dogs, due to an augmented cardiac output from increased venous return and cardiac acceleration. Large doses of sodium nitrite often produce a rise of both carotid and pulmonary pressures with cardiac irregularities, which sometimes terminate in ventricular fibrillation. On excised pulmonary arteries, amyl nitrite and small doses of sodium nitrite produce relaxation. Large doses of sodium nitrite cause a contraction of these vessels, which is suggested is caused by irritation and not true stimulation. The action of amyl and sodium nitrite upon the pulmonary arteries is the same, though less marked, as upon the systemic vessels; however, the effect upon pulmonary pressure is often counterbalanced or overbalanced by the secondary effects of the action upon the systemic circulation.

DIABETES

Benign Glycosuria and Diabetes Mellitus.—J. E. Holst (*Acta medica Scandinavica,* December 4, 1925) by seeking information about the subsequent history of a series of individuals in whom glycosuria was previously demonstrated, attempts to obtain knowledge empirically of the frequency with which the nondiabetic glycosurias occur and the factors which can be used as the basis of an early diagnosis and prognosis in a case of glycosuria. The investigation comprises 352 patients in whom during the years 1907-1918 sugar was demonstrated in the urine. Of these 194 were of the author's own material, who, applying for life insurance in Copenhagen were rejected on account of glycosuria. The other 158 were hospital patients. In 163 of these the subsequent history was traced and in only thirty per cent. could diabetes mellitus be demonstrated after an observation period which for the majority of cases lasted from five to sixteen years, while in the remainder the glycosuria must be regarded as nondiabetic. The author summarizes his conclusions as follows:

Cases of diabetes mellitus discovered by chance often have a particularly favorable course.

The nondiabetic glycosurias can be divided into three main groups: Glycosuria with cyclic hyperglycemia, renal glycosurias and transition cases.

The older function tests for glycosuria (tests for alimentary glycosuria *e saccharo* and *ex amylo*) are useless, as they do not distinguish between the nondiabetic glycosurias and incipient diabetes mellitus. A blood sugar examination should be made in every case of glycosuria which is not of a purely transitory nature.

Glycosurias with normal fasting blood sugar all have a benign course without respect to type. Determination of the fasting blood sugar is therefore sufficient for diagnosis and prognosis and no practical importance can be ascribed to the function tests for differentiating the various types.

Diabetes and Pregnancy.—A. Springer (*Wiener klinische Wochenschrift,* October 8, 1925) calls attention to the close relationship between diabetes in the mother and the giant growth of the fetus, and warns the general practitioner that in the presence of a proved diabetes in the mother it should be borne in mind that the fetus may become unusually large, and that labor should be induced at a time when the mother may be delivered without causing undue difficulties because of the large size of the child. Even though such a procedure, as experience shows, offers the child a reduced chance, nevertheless the course of the labor for the mother will be made much easier, and otherwise, the fate of the child is sealed anyway. If labor is not induced early a Cæsarean section may have to be done, which also gives poor results in the presence of diabetes. On the other hand, when a giant fetus is believed to exist, it is well to think of diabetes in the mother, and the urine should be examined frequently during the puerperium even in the face of a negative finding, inasmuch as diabetes may become manifest only after some time following the delivery.

Most authors are agreed that the breadth of the shoulders of the fetus is the chief cause of the difficult delivery. The delivery of one or both arms is almost always necessary, and sometimes cleidotomy must be done. Occasionally a Cæsarean section may be necessary even if the fetus is dead.

Diabetes and Commonsense.—George L. Servoss (*Western Medical Times,* January, 1926) says that no other disease requires more commonsense in its handling than does diabetes. Today there is nothing about it that should even startle us. If we cannot accomplish our ends with proper diet we may resort to insulin. In the past diabetics, and many of them, lived out their full score of years. With the advent of insulin and a better understanding of the disease, still more should live in comfort to a good age, and in apparently perfect health. A diabetic properly handled need not be a morose individual. His wants are supplied. Of course he cannot take extensive carbohydrate or fat excursions and his proteins may be cut down some, but he will enjoy a rather generous diet and will get as much enjoyment out of life as does the individual whose islands of Langerhans are all intact and functioning. Remember that diet is just as important as ever and just because your patient is taking insulin, don't tell him he can increase the dose a bit and eat more. That may be his undoing, for overeating even in the face of insulin, may be followed by acidosis or other complications, or may call for subsequent insulin increase; quite the reverse of what is desired. "Safety first" is the cardinal rule in the treatment of every case of diabetes and he who is conservative and uses commonsense will go a long way toward an ultimate success. The study of diabetes is no trifling affair, nor is that of insulin therapy and he who employs the agent with little or no study, or he who knows little or nothing of the proper dietary treatment of the disease, would better make no effort to treat a single patient so afflicted. This has been agreed upon by all the authorities. So, if you have not a full comprehension of diabetes and its proper treatment, do not attempt its care, for if you do you will be unfair to yourself and patient alike, and will be very liable to meet with absolute failure. With diabetes, more than with probably anything else in the whole art of medicine, does "those who know" succeed, or "where those who know not" fail.

Diabetes.—I. C. Brill (*Northwest Medicine,* November, 1925) says that aside from its historic interest, starvation no longer has a place in the therapeutics of diabetes. Its sole function (rendering an obstinate case sugar free) is now more easily and far more profitably accomplished by the use of insulin. The principle of undernutrition, however, is just as valuable today as it was at its first introduction by Dr. Allen ten years ago. But, like other therapeutic measures, its greatest usefulness is realized only when employed upon proper indications. It has already been pointed out that diabetes patients may be divided roughly into two groups: the undernourished, and the obese. In the former group are included most of the cases of diabetes in the young, especially children. The latter group is composed largely of patients at middle age or over, with a tendency to a mild and chronic course. It is in this group of patients that a subbasal diet leading to a moderate degree of undernutrition brings the best results. In this type of patients practically complete cure may in some instances be obtained by dietary measures alone, by a judicious application of the principle of undernutrition. On the other hand, in the young and already undernourished patient the prolonged application of the principle of undernutrition is apt to lead to disastrous results.

The maintenance diet is the ultimate goal in all cases of diabetes. In the undernourished group and in practically all cases of juvenile diabetes the maintenance diet must be instituted from the beginning, the process of desugarization being accomplished by the use of insulin, rather than by further increasing the state of undernutrition. The maintenance diet in any given case is determined at the outset by estimating the patient's basal caloric requirement and adding to it twenty to thirty per cent. of the total calories, depending upon the patient's activities. The number of grams of protein in the diet is determined by the patient's weight (from two thirds to one gram of protein to the kilogram of body weight for the adult patient, and from one and one half to two grams of protein to the kilogram of body weight for children). The number of grams of fat and of carbohydrates are determined by the Woodyat method. The inability to administer such a maintenance diet to a diabtic of the undernourished group, or to any diabetic at the end of the course of treatment without causing glycosuria constitutes a rational indication for the use of insulin.

The Effect of the Injection of Heavy Metals on Diabetes Mellitus.—In their experiments with heavy metals in diabetes mellitus, Erich Schilling and Rudolph Arnold (*Klinische Wochenschrift,* September 17, 1925) found that the effect on the acidosis was not always the same: in individual cases both the acetone and the sugar disappeared promptly from the urine; in some cases, on the other hand, there was no effect on the acidosis. In cases without acidosis, the effect upon the clinical picture was evident: with the reduction of the blood sugar content, the amount of sugar in the urine was also reduced. In the less severe cases the urine became absolutely sugar free and remained so for two or three days, but the amount of sugar in the urine gradually returned to the former amount. In these experiments the dietary of the patients was not changed. The value of these findings should not be overestimated, as the effect of the injection of heavy metals (preparations of iron, mercury, silver and bismuth) in some cases was purely symptomatic; furthermore, these injections cannot be kept up indefinitely. Nevertheless, these findings are very interesting from the theoretical viewpoint, and in suitable cases these injections served a good purpose.

A Clinical Study of Diabetic Coma.—W. W. Payne and E. P. Poulton (*Lancet*, September 26, 1925), from a study of eleven cases and a review of the current literature, conclude that a definite renal element as shown by oliguria, albuminuria, and urea retention and failure to excrete ketone bodies, and occasionally sugar, is present. In some cases this renal failure is so decided as to cause a marked resemblance to uremic coma.

The cause of the renal failure is by no means clear. It is usually considered that the kidney, in common with other organs, is poisoned by the ketone bodies, and in particular by the diacetic acid. While this poisonous action undoubtedly exists it does not explain why a kidney which has for a long time successfully dealt with large quantities of ketone bodies suddenly fails and permits them to accumulate. Other possibilities must therefore be considered. There are several.

1. The poisonous action exerted by the excess of sugar in the blood.
2. Other toxins may be formed. There is, however, very little evidence of them.
3. The ketone bodies may poison the heart muscle and the circulatory failure may cause renal failure with oliguria and further accumulation of poisons.
4. The preceding polyuria noted in many cases, or the vomiting in others, may completely deplete the water reservoirs of the patient, the kidney thus becoming unable to excrete the poisonous ketone bodies owing to lack of the necessary water.
5. The ketone bodies may be produced so very rapidly that the kidney is unable to cope with them.

The last three factors probably account together or separately for the majority of cases of coma, and also for the different types of cases.

All the cases of diabetic coma reported were young subjects. With efficient insulin treatment the most important cause of death at the present day would appear to be renal failure, as indicated by prolonged oliguria, high blood urea, and the excretion of mere traces of sugar or acetone bodies in the urine. Albuminuria is practically always present and so will not influence the prognosis. After recovery from coma there is no tendency to relapse into coma provided insulin treatment is continued. The ultimate severity of the case, as judged by the amount of insulin required, depends largely on the length of time the patient has had diabetes, if insulin has not been given previous to the coma, because the disease is naturally progressive in young subjects. It is obvious, therefore, that some cases of diabetic coma closely resemble uremic coma.

The occurrence of diabetic coma should be prevented as far as possible by, 1, not stopping the use of insulin suddenly, and 2, the prevention of acute infections, such as sore throat, cold, chill, or temperature, by the wearing of face masks, paraffin and vaseline treatment, prophylactic vaccinations, etc. If infection occurs the insulin must be continued, and if glycosuria and ketosis supervene the dose should be increased and extra carbohydrates should be given for the time being. The bowels should be kept open and plenty of fluid should be taken by the mouth.

The treatment consists in massive doses of insulin twenty to forty units every four hours, and at the beginning an intravenous injection of ten to twenty units may be given if the case is urgent. Large volumes of fluid are necessary to keep up the flow of urine. If the patient cannot take one pint of fluid every hour by mouth, it should be passed directly into the stomach or duodenum through a nasal or Einhorn tube, with the patient lying on the right side. The fluid should be isotonic, sugar, sodium bicarbonate, and a little salt being dissolved in tap water. The bases of the lungs should be watched to see that edema does not develop. The rapidity with which energetic treatment with insulin may cause diabetic coma to pass into hypoglycemic coma without the patient recovering consciousness should be borne in mind.

Diabetic Treatment Simplified.—Frank C. Eve (*British Medical Journal*, June 6, 1925) states that the treatment of diabetes has now become very complicated, and there is a real danger of the main issues becoming fogged in a cloud of bewildering details. The main issues are: 1, the quantity of sugar excreted day by day; 2, the presence or absence of ketones; 3, treatment by regulating the quantity of the diet, or by giving insulin if dietetics prove inadequate; 4, the blood sugar (in special cases). The main practical points regarding insulin are:

1. Insulin is something which somehow enables a diabetic to burn up sugar like a normal person, but does not enable him to store it as glycogen.
2. Insulin can in this way cause the blood sugar to sink to a dangerously low level (hypoglycemia). This can be avoided if the patient always carries about with him eight large lumps of sugar and promptly eats them all if he feels queer after an injection of insulin. Eight average lumps of sugar acts as an antidote to fifteen units of insulin.
3. Insulin is given two or three times a day, just before a chief meal, which if possible should contain one ounce of bread; ten to fifty units daily as the usual range of dose; more is seldom useful.
4. The patient can be taught to inject in into a pinched up skin of the thigh, under weekly supervision.
5. Insulin has to be acid; in a few subjects this causes painful lumps. It is said that neutralization in the syringe by sterile sodium bicarbonate solution of proper strength prevents this irritation and does not impair the action of the insulin.
6. Blood tests with insulin are rarely helpful, for the blood sugar cannot be kept normal in private practice.
7. The risk of giving insulin in unsuitable cases will be practically eliminated without blood tests, a, if you first try to cure all cases by diet alone; b, if ketones are present, and abundant sugar, insulin is surely needed; 3, leaky kidneys (renal glycosuria) are a real but uncommon danger. These cases may be recognized by their uncanny failure to improve with diet, by their good health, by the absence of ketones, and by the absence of glycosuria three hours after a good starchy meal. A blood sugar will decide the matter by showing a low renal threshold for sugar.
8. If in an emergency there is fear of causing hypoglycemia, the insulin may be guarded with sugar, as mentioned above.

In coma, the treatment must be drastic and intravenous injections are needed, starting with twenty to forty units of insulin, forty to eighty grams of glucose in 800 to 1600 c. c. of water. Then you must feel your way by results, but eighty to one hundred units or even more may be needed in the first day. Croton oil, strychnine, and camphor will also probably be indicated.

Exercise in moderation is important in diabetes to help the combustion of sugar to carbonic acid. Bed rest should be prescribed only during starvation or illness.

SYPHILIS

Observations on Congenital Syphilis.—Philip Haskell Sylvester (*Boston Medical and Surgical Journal*, August 27, 1925) gives the following program of treatment.

We give sulpharsphenamine intramuscularly to very young or very small babies, in a dose of g.05, g.075, or even g.1, according to size and weight of the baby, for three doses, then increase by g.05 in each succeeding series of three doses until the baby has received a total of twelve doses at weekly interval. At the end of this first series, the baby is given a vacation of one month, when it returns for Wassermann. If negative, as it usually is, the baby is given a second series of twelve injections, each of about one half the corresponding dose of the previous series, when another month's vacation is given and a Wassermann taken. If this is negative (as it has never failed to be in this group), the baby returns for blood test alone at the increasing interval of three months, six months and one year. In this group of young babies, all those who have once become negative have remained so to date. A small baby critically ill with syphilis, or a syphilitic baby critically ill with anything else, or in a state of severe malnutrition, is treated by mercury alone in inunctions or by a constantly applied binder, until its general condition has been improved to a reasonable degree. Then it is given sulpharsphenamine in very small doses (g.05 to g.075) at weekly or fortnightly intervals, meanwhile continuing the mercury. When in really good condition, the full course of twelve injections is given as above. In older children, the dose is started at g.2 and is rapidly run up to g.4 for a total of twelve weekly injections and the series repeated with a vacation of one month at the end of each series until the Wassermann becomes negative. So far we have had no general reactions, whatever, and no local reactions worth mentioning. To one who has seen the severe general reactions following the intravenous use of neoarsphenamine, and who has been through the shrieking bedlam of a clinic where

it was being given intramuscularly, the peace, quiet, and friendly atmosphere of the sulpharsphenamine clinic are very pleasing. It is my hope and belief that the ease of preparation; simplicity and painlessness of administration; and absolute freedom from severe reaction, will make the comfortable and effective treatment of congenital syphilis possible and convenient in the hands of every general practitioner.

In the presence of certain well known conditions, intravenous arsenic in any form may produce severe crippling and often fatal reactions, and must not be given if these conditions are present: 1. In grave malnutrition from any cause, even syphilis. 2. In any severe infection, particularly of the lungs, as pneumonia or severe bronchitis. 3. In high fever from any cause. 4. In the presence of acute meningeal symptoms. 5. In nephritis.

While neoarsphenamine may be safely given intramuscularly in small doses, under any of the above circumstances, it is probable that the rapid absorption of sulpharsphenamine makes its intramuscular administration just as dangerous as when given intravenously.

Syphilis of Aorta and Heart.—William D. Smith (*Boston Medical and Surgical Journal,* August 27, 1925) says with regard to the treatment of this disease that treatment of aortic and cardiac syphilis should always be begun with mercury and potassium iodide and only after some weeks of such preliminary treatment and a careful consideration of the clinical picture, should arphenamine be used and the initial dose smaller than that generally given, not more than 0.05 gm. to 0.1 gm. of diarsenal gradually increased to not more than 0.3 gm. or the corresponding amounts of neoarsphenamine. If tolerated, then repeated courses should be given as in the treatment of syphilis generally.

Arsenic is a dangerous drug to begin treatment for cardiovascular syphilis and the danger increases in relation to the size of the dose and to the organic changes present in the aorta and heart.

In the management of such cases so many factors are involved, such as the age of the patient, condition of the kidneys, degree of arteriosclerosis, presence or absence of decompensation, etc., that no definite routine can be laid down or followed and the type and intensity of treatment must be determined by the experience and judgment of the clinician. In cases with marked renal insufficiency, arsphenamine may be a safer drug than mercury.

In the treatment of syphilis, we should not forget that the patient has a damaged heart and that the general management of the case in regard to rest, avoidance of strain, digitalis, etc., may be as important in determining the duration of life as the treatment of the syphilis itself.

Occasionally a case may be seen in such desperate condition and with such clearcut indication for treatment that one is justified in instituting the most intensive treatment including arsenic from the start in the hope of correcting a pathology which if it persists, means the speedy death of the patient.

In general, the author says he has become sceptical of striking benefit from arsphenamine when the patient shows no symptomatic improvement from mercury and iodide, but, none the less, such a case should be given the benefit of arsenic therapy, and occasionally, in spite of the failure of the older drugs, improvement occurs.

Interstitial Keratitis.—Maud Carvill and George S. Derby (*Boston Medical and Surgical Journal,* August 27, 1925) have tried to ascertain how much may be accomplished by thorough antisyphilitic treatment in cases of interstitial keratitis. Opportunity was afforded by the fact that since 1910 the antisyphilitic treatment was placed in the hands of a special clinic and a special worker was detailed from the social service department to follow up the cases. Comparison is made between the results in one hundred cases prior to that date, in which the antisyphilitic treatment was desultory, and 222 cases since that date, the former known as untreated, the latter as treated. In seventy-four per cent. of the treated cases the vision of the better eye was 20/30 or better, while in the untreated only thirty-eight per cent. attained a similar amount of vision. In the treated only one per cent. was below 20/100; in the untreated fourteen or fifteen per cent. show 20/100 vision or less. The figures seem to show that intensive antisyphilitic treatment exerts some influence in preventing the involvement of the second eye, or in making the attack in it less severe. It also seems to have a striking effect in preventing recurrences.

Value of Specific Treatment in Cardiovascular Syphilis.—Bernard I. Goldberg (*Boston Medical and Surgical Journal,* October 22, 1925) says that a greater percentage of subjects have cardiovascular syphilis than has been believed, and that a negative Wassermann does not exclude its presence as this test has proved negative in an appreciable number. These cases should be subjected to a definite and persistent course of combined antisyphilitic treatment, arsphenamine, or allied arsenicals, in the early cases, arsphenamine and mercury in the advanced ones. More caution is required in those more or less advanced, but, whenever possible, arsenicals should be given as such treatment is by far the most effective. Antisyphilitic treatment has been proved to have resulted in the amelioration of symptoms.

Effect of Heat on Heart Extract Used as Antigen in Wassermann Test for Syphilis.—S. L. Leiboff (*Journal of Laboratory and Clinical Medicine,* November, 1925), found that the beef heart used in the preparation of antigen for the Wassermann test may be boiled or even heated in the autoclave under fifteen pounds pressure for an hour without impairing the antigen obtained by extraction with alcohol. The meat may be extracted with hot alcohol without injury to the antigen. A method is recommended for preparing an antigen at high temperatures.

Prolonged, Curable Albuminuria in Syphilis.—C. Laurent (*Presse Médicale,* May 30, 1925), among 500 syphilitic patients whose urine had been examined at each visit, found fifteen of prolonged, curable albuminuria. The initial lesion dated back from one to fifteen years. In some instances rather vigorous treatment had been given. The arsenicals do not act as promptly as usual on these albuminuric cases, most of the author's cases requiring three to five courses of arsenical injections to clear up the albuminuria. All but one of the fifteen cases were free of all other evidence of nephritis such as edema, casts, polyuria, and headache. Yet the albuminuria sometimes reached twelve or fifteen grams per litre. Diet had no effect on the albuminuria, which gradually subsided under antisyphilitic treatment. The duration of the albuminuria ranged from two and a half months to seven years. Several cases were kept under observation for two years after evidence of the albuminuria, and none of them relapsed. The condition would appear to be pathologically a syphilitic nephritis, but not clinically, since there is a characteristic absence of the clinical evidences usual in nephritis. Antisyphilitic treatment should be tried out persistently in all obscure albuminurias uninfluenced by diet or other ordinary treatments.

The Vernes Test for the Diagnosis of Syphilis.—Leon H. Cornwall (*Journal of Laboratory and Clinical Medicine,* July, 1925) has collected the records of the Vernes and Wassermann tests on 1466 blood sera and spinal fluids in order to make a comparative study of the relative interpretative value of the two procedures, rather than a mere numerical comparison of their results. This comparison shows that the Vernes reaction is a valuable addition to the serological procedures for the diagnosis of syphilis, especially useful in determining the effect of therapy. Successive results illustrate graphically whether the infection is progressing, remaining stationary, or regressing.

Further Observations on the Possibility of Cure of Syphilis in the Rabbit with Arsphenamine.—Alan M. Chesney and Jarold E. Kemp (*Journal of Experimental Medicine,* July, 1925) found that rabbits treated with arsphenamine early in the course of the experimental infection, from forty-nine to fifty days after inoculation, were rendered free of popliteal lymph node infection and were found to be uniformly susceptible to a second infection. Rabbits treated late in the course of the disease, 181 to 291 days after inoculation, were rendered free of lymph node infection but were refractory to a second infection in seventy-five per cent. of the cases. Untreated syphilitic rabbits were found to exhibit lymph node infection 265 to 420 days after inoculation and to be uniformly refractory to a second infection. In animals treated either early or late in the course of the infection but not reinoculated, lymph nodes were found to be sterile as late as 275 days after the last dose of arsphenamine. The authors suggest that the refractory state in rabbits may be explained by the existence of an acquired immunity which persists after the abolition of the disease, rather than to the persistence of the first infection. It would appear that it is possible under certain conditions to reinoculate rabbits and produce generalized infection without producing any lesion at the portal of entry.

A Microreaction for Syphilis.—Meinicke (*Monatsschrift für Kinderheilkunde,* January-February, 1925) describes the technic of his microreaction for syphilis in the following manner:

The blood specimen is obtained in the usual way. It is allowed to flow into a capillary tube which is sealed at one end. The tube is then allowed to lie horizontally for several hours or until the next day, when it is placed in a centrifuge tube with its sealed end downward for centrifugalization. In this way the blood clot sinks in the tube, covered by clear serum. The tube is broken within the area of the serum which is then blown out on a glass slide. The author has two glass tubes, one containing one c.c. of his balsam extract, and the other containing ten c.c. of a three per cent. sodium chloride solution, and both are heated to 45° C. The salt solution and the extract are then mixed by pouring them back and forth three times. The dilution of the extract is put into a cup, from which a drop is taken with a large loop and carried to a glass slide. With a small loop, a drop of serum is taken and rubbed up in the large drop of the extract dilution. When the mixture is thoroughly mixed, it is covered with a cover glass and the reaction is completed.

The specimen is allowed to lie at room temperature for one hour, after which the edge of the cover glass is smeared with warm vaseline. The observation of the reaction is made in the dark field. Negative reactions show a grayish base, upon which minute light points are seen in a most lively motion. These minute points are very close together and cover the field uniformly. Marked positive reactions show a deep black base, without the minute dancing points, but with thick, highly refractile starshaped clumps in agglutination. Weakly positive reactions show uniformly spread, smaller starshaped clumps, and between them a greater or smaller number of dancing tiny points.

This microreaction is exceedingly simple and, according to the author's claims, just as reliable as the macroreaction, that is, his clouding reaction.

Comparative Tests With the Wassermann Reaction, the Precipitation Reactions of Sachs-Georgi and Dold, and the Meinicke Precipitation Reaction.—As a result of the comparative tests on more than five thousand sera, that were carried out with the Wassermann reaction and the Sachs-Georgi reaction, and also with the Wassermann, Dold and Sachs-Georgi reactions, and with the Wassermann, Meinicke and Sachs-Georgi precipitation reactions, respectively, and with all four reactions, the following conclusions are drawn by Clara Schuler (*Schweizerische medizinische Wochenschrift,* October 1, 1925):

The method of Bordet-Wassermann gives the greatest number of positive results in cases of certain syphilis and at the same time the least number of nonspecific reactions in control cases. The most favorable results with the precipitation methods (the sigma reaction was not tried) were obtained with the Sachs-Georgi method. In agreement with other investigators, it was found that at the present time it is the best method of control for the Wassermann reaction. The Sachs-Georgi test sometimes gives nonspecific results in tuberculosis, arthritides and enteritides, but far less frequently than the two other methods. These only have the questionable advantage of early reading. However, the test is not very easy in both reactions even for the experienced worker; in questionable positive cases it may even provide great difficulties. These methods cannot be left to the general practitioner.

In regard to the question, as to which of the individual methods is the most useful to the general practitioner, the carrying out of any one of these procedures outside of the laboratory must be emphatically warned against. In every serum reaction, especially in the study of syphilis, not only is an extensive experience necessary, but what is more important, the simultaneous working with a very large number of sera is necessary. Only when a large number of strongly positive and strongly negative reacting sera are examined together, is it possible to render a definite opinion as to the weakly positive and doubtful cases, respectively. A certain centralization, therefore, appears to be absolutely necessary for the syphilis reaction. In the laboratory, the carrying out of one or the other precipitation reactions as a supplement to the Wassermann reaction is desirable. In this way, cases that react negatively to the Wassermann reaction and show a positive precipitation reaction, may possibly be followed up further after provocation, and still be recognized as syphilis. But in such cases great care must be observed. According to the author's experience, such cases are reported as doubtful.

The Swift-Ellis Treatment.—Chaille Jamison (*New Orleans Medical and Surgical Journal,* January, 1926) says that it is in the meningeal types that intraspinal therapy has its greatest value and its least in the parenchymatous. It is useless to employ it in established paresis: it may arrest tabes in its progress, but cannot cure it: vascular neurosyphilis gives rather poor results, and unless the spinal fluid shows the changes of an accompanying meningeal involvement the rationale of this particular form of therapy is not evident. Cerebrospinal syphilis, using the term in its restricted sense, usually offers a good outlook.

THERAPY

Bismuth Treatment of Acute Mercurial Poisoning.—A. Landau, I. Marjanko and M. Fergin (*Presse Médicale,* December 9, 1925), after three years' experience, have come to consider bismuth almost a specific in mercurial poisoning. It yields eighty per cent. of recoveries. One patient recovered completely in spite of anuria of seven days' standing. The treatment consists in giving by mouth cachets of bismuth subnitrate and of bismuth subcarbonate, 6.75 gram, four to six times a day. The other measures customary in such cases are also used, such as wet packs, ten per cent, glucose solution intravenously, five per cent., glucose solution by enteroclysis, and heart stimulants. Rhubarb is also given to counteract the constipating action of the bismuth. The diet is reduced to tea with sugar and orange juice, followed by a diet low in proteins. The prognosis in mercurial poisoning depends, in particular, on the rapidity of onset and duration of the anuria. The azotemia is less important, recovery having occurred in spite of an azotemia of seven per cent. A fatal influence lies in the infections that invade the extensive surfaces of ulcerated mucous membrane in the digestive tract. The obstinate vomiting, bloody diarrhea and severe pains which preclude the taking of food, dehydrating the system and weakening the heart, seem to be secondary to these infections. The benefit from bismuth seems to result from its ability to prevent the onset of these infectious complications, although it may be that there is also a specific chemical action of the bismuth on the mercury, with the formation of stable, harmless compounds.

Treatment of Rheumatoid Arthritis by Intramuscular Injection of Guaiacol, Iodine, and Camphor.—S. Watson Smith (*British Medical Journal,* October 10, 1925) obtained satisfactory results with the intramuscular injection of guaiacol, iodine, and camphor dissolved in oil in nine cases of rheumatoid arthritis and articular fibrositis, other than the postinfective, gouty and gonorrheal forms. The cases ranged between the early and the subacute and the rigid and deformed chronic case. In four cases autovaccines were of no value. All had the various other methods of treatment usually employed. One showed an eminently satisfactory result. Three other patients were definitely relieved. The result in another case was good. Four patients were benefited by a short course of injections.

The author does not suggest that the oil should displace vaccine or other treatment, but rather that it should be employed along with those other general and local means commonly used. The oil is made up in ampules, each containing ten per cent. guaiacol, ten per cent. iodine, and 5 per cent. camphor. The injections are given into the gluteus muscle, or, better still, deeply into the vastus externus about the middle of the thigh, repeated every second or third day.

In no case was there any serious general reactions or after-effect; there was some pain and stiffness in and around the affected joints twenty-four hours or so after the injection, with malaise and slight rise of temperature; one came to expect it, but it was transient, and there was no evil effect other than this. The urine should be tested and, as far as possible, disease of the kidneys excluded before commencing the treatment, and again, occasionally, during its continuance. The highest dose given at any one time was 1.0 c.c.; 0.25 c.c. was injected as an initial dose, and this was increased quickly till 1.0 c.c. was reached; this quantity was then continued with, being repeated every third day or, when thought necessary, every second day.

Toxic Effects of Lead Administered Intravenously.—No one hitherto has had an opportunity of observing the toxic effects in the human subject of measured quantities of lead administered intravenously at known intervals. The accuracy of the observations reported makes them of some importance in any consideration of lead poisoning. Some two hundred patients were given injections by W. Blair Bell, W. R. Williams, and L. Cunningham (*Lancet,* October 17, 1925) in the course of the treatment of malignant neoplasms. The actual form of the lead administered varied considerably from time to time, but the last fifty-eight cases were treated almost entirely by intravenous injections of metallic lead in colloidal form. In the early cases lead acetate, lead iodide in a partly colloidal state, and compounds of lead with thyroidin and with hemoglobin were used. During the treatment and before it was commenced complete and careful analyses (microscopical and chemical) of the blood and urine and hepatic functional tests were made at intervals. The toxic effects of lead were noted on the following systems and organs: 1, the blood and blood-forming organs; 2, the alimentary system; 3, the nervous system, including the retina; 4, the kidneys; 5, the liver. The susceptibility of the individual, the body weight, the age and sex of the patient, and the size of the malignancy were all taken into consideration, and it was found that these factors may interact so as to produce a complex arrangement that is impossible to estimate in any statistical manner, and it is this that makes treatment of malignant disease with lead extraordinarily difficult.

Small doses of lead given over a long period of time produce a dangerous cumulative effect. On the other hand a few large doses administered at long intervals, considerably exceeding in total quantity of lead the amount given in small repeated doses, may, after the initial symptoms, leave no bad effect whatever.

Blood changes.—1. Lead causes changes in the erythrocytes. There is punctate basophilia, which may appear within a few hours of the initial dose. Anemia and its accompaniments, polychromasia, anisocytosis, and poikilocytosis occur later. This anemia may be only temporary, or, if bone marrow be involved, may persist.

2. Leucocytosis has frequently been observed, especially when the blood has been examined shortly after an intravenous administration of lead. Leucopenia occurs occasionally. Neither of these phenomena appears constant.

3. A slight relative lymphocytosis may occur, but this is not generally marked.

4. There is a definite increase in the number of granular forms of leucocytes.

5. Anemia is a consequence of the long continued administration of lead, and it is accompanied by the usual symptoms of that condition—namely, headache, lassitude, and palpitation. In women there may be amenorrhea, which is not constant, and depends on many circumstances.

Alimentary system.—1. Blue line at the gum edge is rarely seen when lead is administered intravenously.

2. Nausea and vomiting appear to be dependent on the amount of lead administered, but occur after a smaller total quantity when given in massive doses, rather than after the long continued administration of small doses.

3. Intestinal colic occurs with considerable frequency after the administration of massive doses; it is not seen after the long continued administration of a smaller quantity.

4. Constipation and diarrhea have not been observed as definite phenomena supervening under the treatment adopted.

Nervous system, including the retina.—1. Psychopathies may occur after the intravenous administration of lead; they are, however, rare.

2. Neuropathies do not occur when lead is administered in the manner mentioned.

3. The retina may be affected; in these circumstances it is probable that it is a concomitant of renal involvement.

Kidney.—1. The toxic effect of lead on the kidney as the result of intravenous therapy is sufficiently frequent and of such magnitude as to require the greatest caution in the administration of this drug, especially in large doses.

2. The functional impairment caused by many small doses is smaller in degree but more permanent than that caused by occasional large doses.

3. The earliest indications of renal failure appear to be: a, diminution in the quantity of urine secreted; b, the presence of albuminuria; and c, the presence of edema.

4. A rise in blood urea does not occur, as a rule, until the damage is sufficiently great to be detected clinically. Changes sufficiently great to be of value have not been observed in the urea concentrating power of the kidney.

5. As in nephropathies due to other causes, it is difficult to correlate functional impairment with pathological change.

Liver.—Pathological changes are not so marked in the liver as in the kidney, and the main impairment of function seems to be connected with the bile producing mechanism.

In general it may be said that the administration of lead is a form of treatment, that should never be attempted by those who have not complete laboratory facilities at their disposal, and who have not studied for some time the actual treatment of patients.

A Pharmacodynamic Study of the Anthelmintic Properties of Two Oils of Chenopodium.—A. Richard Bliss, Jr., (*Journal of Laboratory and Clinical Medicine,* March, 1925) undertook this investigation because of the inadequate supply for human and animal medication of the oil of Chenopodium (American oil of wormseed), and the resulting high price of the Maryland oil of chenopodium, which is preventing the use of the drug in the treatment of domestic animals. The common ascaris of the dog was used as the test worm in determining the anthelmintic properties of the three oils tested, which were respectively oil distilled from plants from Carroll County, Maryland, from Adams Co., Illinois, and from cultivated wild wormseed plants in Adams Co., Illinois. The result of this study showed that oil of chenopodium properly distilled from plants cultivated in the middle Western States is as efficacious in dogs against ascarides as the Maryland oil of chenopodium. On the basis of these experiments Bliss feels that the findings would apply equally well to man.

Experimental and Clinical Observations on the Actions and Therapeutic Uses of Ethylisopropylbarbituric Acid.—D. E. Jackson and Louis A. Lurie (*Journal of Laboratory and Clinical Medicine,* November, 1925) report the use of the calcium salt of ethylisopropylbarbituric acid as a hypnotic. It is a white, sandlike powder which is sufficiently soluble in water to permit of its experimental use by intravenous injections in animals. Experiments on dogs are described showing its action on the respiration and circulation. In animals, the equivalent of a medicinal dose produced but little action on the circulatory system. Very large doses of the drug may be injected intravenously without causing the death of the animal, but when death does occur, it is due to central respiratory paralysis. Consequently, the treatment for poisoning with the substance should consist of respiratory stimulation or artificial respiration. The action of the drug, when given in therapeutic doses, is almost entirely on the central nervous system and especially the cerebrum. In animals, there is an overpowering desire to lie down quietly and sleep. The drug has been used in a great variety of cases clinically by many physicians, with no untoward effect on the heart, lungs, or kidneys. The outstanding feature in all cases is the ease with which a refreshing sleep is produced, without the usual feeling of lassitude and torpor the next day. This drug has proved of value in curing patients of the habit of taking hypnotics, as it not only produces sleep the night it is given, but its sedative action persists so that as a rule the patient will be able to sleep the following night without resorting to the drug.

Lipiodol in Neurosurgery.—A. S. Maclaire (*American Journal of the Medical Sciences,* December, 1925) reports a case in which the intraspinal damage was definitely increased by the use of lipiodol. This preparation, which is a fifty-four per cent. solution of metallic iodine in a vegetable oil, is almost nonabsorbable and can be said to be irritating if left within the subarachnoid space over an indefinite period of time. Hence it is advisable not to use it as a means of localization except as a last resort, and only when laminectomy is to follow in a few days. The oil should then be removed from the intradural space.

Bacterial Vaccines in Asthma.—Grafton Tyler Brown (*American Journal of the Medical Sciences,* January, 1926) contributes a valuable paper to this controversial subject. His results in one hundred and forty-four cases of asthma treated with bacterial vaccines were: Seventy-four, or fifty-one per cent., completely relieved of asthma; fifty-six, or thirty-nine per cent., improved in varying degrees, and fourteen, or ten per cent., unimproved. His method of diagnosis and treatment should be read in the original.

Medicolegal Notes.

IDENTIFICATION OF X RAY PHOTOGRAPHS

The Illinois Appellate Court holds, Wicks v. Cuneo-Henneberry Co., 234 Ill. App. 502, that in an action for personal injuries testimony of the plaintiff's physician that he had examined plaintiff's hand and had x ray photographs taken which he produced in court, and further testimony that the photographs were true and correct presentations of plaintiff's hand at the time they were taken, was sufficient identification of the photograhps to allow their admission in evidence.

ADMISSIBILITY OF DECLARATIONS AND DESCRIPTIVE STATEMENTS OF INJURED PERSONS

The Minnesota Supreme Court holds, Lund v. Chicago, R. I. & P. Ry. Co., 204 N. W. 628, that mere descriptive statements of a sick or injured person as to the symptoms and effects of his malady are only admissible under the following circumstances: First, they must have been made to a medical attendant for the purpose of medical treatment. Second, they must relate to existing pain or other symptoms from which the patient is suffering at the time, and must not relate to past transactions or symptoms, however closely related to the present sickness. Third, such statements are only admissible when the medical attendant is called upon to give an expert opinion based in part upon them.

The declarations of a party himself, to whomsoever made, are held to be competent when they are expressive of existing pain or suffering. Such are regarded as exclamations or complaints which are the spontaneous manifestations of distress. But descriptive statements of existing pain or suffering are only admissible when made to a medical attendant for the purposes of medical treatment.

DEFENDANT'S DECLARATIONS AGAINST INTEREST IN NEGLIGENCE CASE

The Oklahoma Supreme Court holds, Bungardt v. Younger, 239 Pac. 469, that generally the skill required of surgeons in performing an operation is ordinary skill, and the care required of them in the subsequent treatment of the patient is ordinary care. In actions for negligence in cases of this character plaintiff has the burden of proving want of ordinary skill in the performance of the operation, or want of ordinary care in the subsequent treatment, and nonsuccess or unsatisfactory results of the operation will not alone establish the essential elements of legal detriment. Where, however, there is evidence of facts attending the operation or the subsequent treatment which in the ordinary affairs of life would bear a causal relation to the demonstrated result, and those facts are of such nature as to be comprehensible to laymen of ordinary intelligence, the probative value of such evidence and the causal relation of such facts to the alleged legal detriment are questions of fact for determination by the jury under proper instructions. In such a case, where expert evidence is required to make out a cause of action, and there is evidence of declarations against interest proved to have been made by the defendant, himself an expert and assuming to treat the plaintiff with ordinary care and skill, which, with all the other facts and circumstances in evidence, tends to show a want of ordinary care and skill in such treatment and to show a causal relation of such want of care and skill with the resultant detriment complained of, it is held that such evidence is sufficient to entitle the plaintiff to go to the jury.

INFERENCE CANNOT BE BUILT UPON INFERENCE IN MALPRACTICE CASE

The Missouri Supreme Court holds, Cardinale v. Kemp, 274 S. W. 437, that all expert testimony must be predicated upon facts or conditions conceded to be true or existing or assumed to be established by other testimony, and that necessity excludes the possibility of basing one opinion upon another opinion. Therefore, in an action for malpractice, the negligent act alleged being the cutting plaintiff's eyeball with a sharp instrument while removing a cyst from his left eye, causing the eyeball to shrink and destroy the sight thereof, it is held that, there being no proof that there was a cut of the plaintiff's eyeball by the defendants, that fact could not properly be proved by an opinion. To assume it without any proof as the producing cause of the condition found would be, it is held, to have the experts find the facts and decide the case on guess work.

The plaintiff, it is held, could not make out his case by building one inference upon another. It could not be inferred that the scar found upon the eyeball was caused by a cut, and further that the defendants caused the cut, and still further that the cut caused the loss of the eye.

RIGHT TO RECIPROCITY LICENSE

A physician was permitted to take his examinations before the board of medical examiners of the state of Michigan upon a certificate from a college of medicine which was a member of the Associtaion of American Medical Colleges that he had passed his final examinations by the faculty and would be recommended to the board of trustees for graduation. In mandamus proceedings to compel the board of medical examiners in California to issue the physician a license to practice in California the sole question was whether or not in legal contemplation he was possessed of a diploma from the Michigan medical college at the time he was permitted to take his examination before the board of medical examiners of Michigan. It appeared that although the college diplomas were not issued to the graduates when petitioner took his examination before the state board, they were issued several days after, and before he was given his certificate to practice in Michigan. The California District Court of Appeal, First District, held, Levin v. Board of Medical Examiners, 239 Pac. 410, that the physician was entitled to a reciprocity license to practice in California provided all other requirements were satisfied, on application under section thirteen of the California Medical Practice Act. The court said: "The certificate was to all intents and purposes the equivalent of a diploma. It certified that petitioner had passed his final examinations, and he was therefore entitled as a matter of right to a diploma. Moreover, the diploma was in fact issued to him before he was granted his license. To say that under such circumstances he was not possessed of a diploma entitling him to take his examinations would be to put a narrow construction upon our statute, which requires the filing of a diploma prior to the taking of examinations. The statute should receive a reasonable construction, and the spirit and reason should prevail over the letter." Mandamus was therefore granted.

EVIDENCE OF SUBSEQUENT X RAY BURN NOT ADMISSIBLE

Where a defendant was charged with negligently using an x ray machine on plaintiff, so that the latter was badly burned, the Mississippi Supreme Court holds, Unger v. Grimsley, 103 So. 341, that evidence that two years after the injury complained of the defendant burned another person while using a different x ray machine and under entirely different circumstances, was inadmissible and highly prejudicial.

Some Notes on Cancer*

V.—On Metastases and Other Distance Effects in Cancer

WILLY MEYER, M.D.
New York

Whenever surgeons have felt the urge of making the attempt to fathom the problem of cancer, they have usually approached the subject not from the more detached viewpoint of the pathologist and the laboratory student whose original work principally purposes the advancement of science, but from the clinical point of view of sympathetic commiseration of the unbearable suffering with which they found themselves continually confronted; and how frequently with no satisfactory means at hand for its alleviation!

I am following where others have led. My inquiry is directed at the whole range of cancer questions and allied ramifications, at the entity "cancer problem" in its entirety, at details only as far as unavoidable in the broader endeavor.

The place to test conceptions is the clinic. It was this reflection that became the guiding thought in the shaping of the present series of articles. A number of papers of general review and on the theoretical questions involved will be followed by a paper on practical questions. In the former the foundation is being laid for the latter, in which the conceptions developed in the preceding papers are tested on personal clinical experiences and on the clinical experience of others taken from the literature, this inexhaustible treasure trove of the best thought and experience of the world.

The support from the literature thus far advanced for our contentions has been principally of a general character. It now becomes necessary to go into the detail of these matters.

Regarding the question of growth in cancer[1] the theses have been advanced in previous communications[2], that there seems to be good reason for believing "new growth" a passive phenomenon due to enforced cell division, such enforcement presumably resulting from the presence in a group or groups of cells of a chemically changed focus (or foci); and further good reason for believing the various types of new growth, from hyperplasia through all the intermediate benign stages up to and including malignancy, to be reactions to and symptomatic of merely quantitative differences in the degree of concentration in the focus of the chemical substance which enforces the cell division.

By means of numerous quotations from the literature we tried to establish in the third communication of this series the point that throughout this entire proliferative territory from hyperplasia to including malignancy there have been found no morphologically discernible lines of demarcation anywhere, but that from end to end all the clinically distinguished types of proliferative growth flow into one another by imperceptible gradations. The inference therefrom would appear unavoidable that the degree of concentration of the chemical substance in the focus must also vary by imperceptible gradations, if this substance is to be capable of enforcing a reaction of similar gradations in the tissue.

Thus, by seeming to turn in a circle, we arrive at the conclusion that from the moment the degree of concentration of the division enforcing substance in the focus exceeds the limit of physiological tolerance of the normal cells, we would seem to witness the onset of proliferation of the affected cells, with simple hyperplasia as the threshold proliferation.

At this point the demand for space of the younger generations of new cells is believed to be still easily satisfied. Hence there is probably little crowding of the new cells at the focus and consequently their passive outbound movement would be comparatively slow. At the rate at which the concentration of the division enforcing substance in the focus increases—why it should do this will be discussed later—so would, according to our contention, also increase the rapidity of cell multiplication, in other words, so would increase the crowding of new cells at the focus, and therewith the energy behind the passive outward bound movement of these cells, the "cell *vis-a-tergo*" (v. Bardeleben (1) p. 500). This process, increasing by imperceptible gradations, becomes clinically discernible at intervals and is described successively by the clinical terms of hyperplasia, inflammatory new growth, benign tumor growth, carcinoma, carcinosarcoma, sarcoma, the differences from our point of view consisting largely in the phy-

*Received for publication March 16, 1926.

[1]The term "cancer" will, as before, so also here be employed to encompass not only every growth of malignant character, but also the whole process leading up to it.

sical factor of more or less urgent cell crowding[3] Biologically considered, there seems to exist no actual difference between sarcoma and carcinoma, or for that matter between an adenocarcinoma and a squamous cell carcinoma, and according to numerous previously quoted authors no difference in principle between malignant and benign growth. "Clinical distinctions of this character," according to Watermann (2) (p. 380) "are meaningless for the biological problem."

Let us now assume again the primary presence of the focus. One might call the focus, as Legrand (3) (p. 109) did in another connection, "a medium in the medium." Why and how it presumably originates and what it probably contains to produce the effects discussed in the present article, are questions that will be taken up in later chapters. Here our first concern is to make the existence of the focus look probable. For that purpose we shall analyze its effects. These effects appear first as influences exerted upon its immediate surroundings, the tissue enclosing the microscopic focus; and, second, as distance effects: effects in the near distance and effects in the far distance, the latter the socalled metastases. After the effects have been discussed in detail, we shall then argue back from the effects to the focus.

We said, let us assume again the primary presence of the focus. Let us further assume the division enforcing substance in the focus to have gradually reached a concentration capable of producing the degree of cell multiplication, the degree of cell crowding, the degree of passive movement of the cells away from the focus and the degree of their passive accumulation commonly described by the hazy term of malignancy.

If we now examine the developments that have taken place, we perceive in the tissue a focus of microscopic size and radiating therefrom—filling up the fissures of the tissue and lying loosely in its interspaces, later also in the preformed lymph channels, (Fuss 4)—irregular strings and variously shaped bodies of passively accumulated cancer cells. Ribbert (5) (p. 330): "Cancer cells are lying loosely in the alveoli and in no connection whatever with the walls of the same."—Geipel (6): "From a carcinoma of the stomach the lymphatics of the skin were completely filled up with cancer cells, but their walls were in no way changed."—M. B. Schmidt (7) (p. 38): "In my specimens . . . when emboli of cancer cells completely filled the lumina of lung arteries of smaller caliber, the endothelium of the latter could in many instances be demonstrated to be intact."—All these loose cells are presumed to be in passive motion away from the focus, supposedly pushed outward from behind by the demand for space of the latest generations of new cells. v. Hansemann (8) (p. 192): "Cancer cells exhibit lazy ameboid movements; they throw out plump pseudopods and change their shape . . . Their motility does not equal the motility of leucocytes."

It stands to reason that on being forced past fixed tissue cells, fibres and other tissue elements, the moving loose cells will have to overcome more or less resistance. Eventually, therefore, it would seem that the back pressure from the body of displaced moving cells upon the newly formed cells at the focus would have to become unavoidably equal to, if not greater than, the outward pressure of the newly formed cells in their demand for space. This, of course, is mere speculation. If, for the sake of the argument, we assume it to be correct, then the movement of the cells at the centre would correspondingly slow up; the cells there would remain exposed longer to the influence of the focus and there would seemingly be for the internal condition of these cells a chance of coming to equilibrium with the condition of the focal medium. Greischer (9) injecting experimentally fatty solutions of azo colors, of indol, of skatol, and other substances found the character of the induced proliferation as to massiveness, intensity and extent, to depend on the longer or shorter time of exposure of the epithelium to the injected substances. . . . The focal medium would then cease to be a stimulus of division for this group of cells, and there being no further young cells demanding space, the group would come temporarily to rest. This result of our assumption squares with the observation of Virchow (10) (p. 50) that "the first existing mother nodule grows to a certain size and then stops growing."

The focus would now have grown in size. It would consist of the original focus plus the fringe of loose, but now resting cells which are supposed to have acquired by inward and outward diffusion the same degree of chemical change that characterized the original focus. But between the limits of this enlarged resting centre and the margin of the new growth the multiplication of cells would necessarily continue, because of the disharmony in all likelihood existing between the condition of the cells arrived more or less changed from the centre and the local medium into which they were being pushed out. This disharmony would obviously be greatest at the margin, where the changed moving cells come in contact with the more or less normal general medium.

Here, at the margin of the new growth, quite a variety of variously conditioned tissue cells would seem to be present: 1, loose, changed cells, newly arrived from the centre, which might be of epithelial or of connective-tissue origin; v. Hansemann (11) (p. 36): "The law is of general application that proliferative stimuli never confine their effect to a definite tissue, but cover a certain space and affect all the tissue therein contained irrespective of type."—Opitz (12): "I have yet to see the carcinoma in which epithelial proliferation had not been associated with connective tissue proliferation"; 2, the fixed cells of the marginal tissue; 3, loose, changed cells in mitosis, the division being enforced by their differing in condition from the condition of the marginal medium. This medium being, according to our argument, nearer to normality than the cells, the arriving loose cells would evidently here at the margin undergo a change in the direction of normality, and in the course of the change would give off to the medium the chemical substance impressed upon them at the centre. These loose cells, after having originally been dedifferentiated at the centre when as normal cells they first came under the influence of the focus, would now seem to be redifferentiated at the margin on coming under the influence of a near-normal medium, they changing back to as near an

[3]The chemical questions involved will be fully discussed in the next paper.

approach to their previously normal state as their injured condition and the condition of the medium will permit;—Böhm (13) (p. 203): " . . . intoxication and detoxication may occur after the analogy of a reversible reaction in the physicochemical sense, the toxic substance absorbed by the protoplasm being returned to the medium at the rate at which the concentration of the toxin decreases in the medium"; 4, fixed marginal tissue cells undergoing mitosis on becoming exposed to the unaccustomed substance in their medium which is given off by the newly arrived loose cells in the process of their redifferentiation. These dividing fixed marginal cells are consequently being dedifferentiated in the direction toward malignancy. Loeb (14) (p. 796): "Through the action, especially of chemical growth stimuli, normal tissues can be transformed into cancerous tissue without the intervention of ulceration."

The marginal cell divisions as previously stated have usually been regarded as the manifestation of their alleged newly acquired powers, or newly awakened latent powers of incessant lawless multiplication; while their advancing into the adjacent tissue has been looked upon as the manifestation of their power of irresistible active invasion. The margin of a malignant tumor was ordinarily considered its growing edge, its living malignancy when the malignant centre had already died. v. Hansemann (8) (p. 103): "In malignant tumors mitoses are generally found in groups, suggesting focal stimuli of proliferation, the groups occurring principally at the margin of the tumor, indicating this part of it as the point of greatest growth."—Ménétrier (15) (p. 181): "It is at the margin of the cancer that we can study what took place at the original lesion."—Stern (16) (p. 230): "The central . . . part of a cancer becomes necrotic, the marginal portion continues to grow."

On the other hand there are authors whose observations have been such as to induce them to form a contrary opinion, namely that cancer cells lose their socalled malignant powers at the margin of the new growth. Gaylord and Clowes (17) (p. 651) quote Petersen as bringing evidence that at the margin the tumor cells "were being deprived of their vitality by some obscure process;" and they themselves observe (p. 658) (17): "Epithelial cells at the margin of the tumor are in some way robbed of their power of destructive proliferation, after which they undergo simple atrophy and gradual absorption by the surrounding connective tissue."

We might note here that our argument is in a way in line with both classes of observations, we having found at the margin cells in process of dedifferentiation, and other cells in process of redifferentiation. Petersen's "obscure process," according to our contention, would seem to be the disharmony existing at the margin between the condition of the cell and the condition of the medium which surrounds it, the disharmony enforcing the adaptation of the cell to the condition of the medium by means of cell division. Legrand (18) (p. 28 ff.): "Protozoa placed in an artificial medium which slightly differs in chemical composition or in temperature, or in other physical properties from the one to which they have been accustomed, multiply and continue to multiply until they have changed the medium and the medium has changed them into mutual harmony. The cells of metazoa [of man for instance (The writer).] act the same way . . ."

As a matter of fact, therefore, the margin of a malignant tumor would seem to be not its socalled growing edge, if that term were used to denote progressive malignant intoxication of the cells. The loose, changed cells arriving at the margin from the focus would seem to keep on dividing "until the medium had changed them and they had changed the medium into mutual harmony," i.e., until on some average level less concentrated or, in other words, less malignant than the focus, equilibrium had been attained between cell and marginal medium. In that event it would be only to about this probably nonmalignant average level that those fixed marginal cells would be changed which happened to come under the influence of the changed marginal medium.

Our deduction that a malignant tumor is likely to be nonmalignant or less malignant at its margin than at its center, and that it may influence the surrounding tissue, would seem to be supported by observed near distance effects of malignant tumors. v. Hansemann (19) (p. 188) found hyperplastic growth of benign character at the margin of, and in continuity with malignant growth. Petersen (20) (p. 604) says: "We certainly cannot avoid assuming that from a carcinoma emanate influences affecting the near-distance."—*idem* (20) (p. 602): "Once a carcinoma has been established, an irritation seems to emanate from it which favors the establishment of new foci . . . In almost any carcinoma we have observed in its vicinity a hyperplasia of that tissue in which the cancer arose."—Orth (21) (p. 50): "Adjacent to genuine tumor formation is found hypertrophic proliferation of epithelial tissue."—Stahr (22) (p. 238): "Collateral hypertrophy can be demonstrated in all sorts of tissues when they adjoin cancerous tissue. Osteoplastic carcinosis is also a near distance effect of the carcinoma."—Watermann (2) (p. 380): " . . . everywhere around an incipient cancer of the integumentum parts of the tissue are frequently found in a state of hypertrophy which may be considered either precancerous, or, with equal justification, not seldom as induced by the growing cancer; for there is no doubting the fact that the incipient cancer exerts an influence upon the tissue surrounding it."—Writing on polarization, Waterman (23) (p. 580) says: "In the process of malignant tumor formation, even before anything like a tumor is discernible, there are already changes demonstrable on the border surfaces (of the cells) . . ." Still more significant regarding near-distance effects are observations made by Goldmann (24) (p. 61), who writes: "Every tumor . . . produces a circulatory apparatus of its own after the preformed vessels have been either inactivated or destroyed. Beyond a doubt, the newly formed vessels are caused by angioplastic stimuli which emanate from the tumor cells themselves. To them we must quite likely also ascribe the distance effect demonstrable on vessels of the tissue adjacent to the tumor. This (near) distance effect is the common property of all types of tumors, of carcinoma as well as of sarcoma and of chondroma. There are enormous corrugated convolutions of young vessels, also long-stretched, pedunculated, tasselshaped vascular pro-

liferations which grow out from afar in the direction toward the tumor. Thiersch has described these phenomena for skin cancers. Again we observe the most extraordinarily phantastic changes in the shape and the lumina of such vessels; one might call them the furthest outposts of the healthy tissue where it faces the advancing new growth. The matter is the more remarkable as not infrequently there is a broad zone of entirely unaffected connective tissue interposed between these phenomena and the margin of the new growth. Circulatory disturbance cannot be the cause of these vascular changes, because the changes are found only on that front of the tissue in question which faces the tumor."

From the point of view of the diminished malignancy or probable nonmalignancy of the margin of a cancer would seem to become understandable also the observation of Palugyay (25) (p. 257) that "the greater the malignancy, the more cells enter into the prophase of mitosis, but the smaller is the number of actually completed divisions." In vitro "it takes a cell thirty-six minutes to perform the mitotic fissure of the nucleus into two daughter nuclei, and additional ninety-nine minutes to finish the separation of the cell plasma," Erdmann (26) (p. 51), that is upward of two hours for the complete cell division. Now according to our contention "great malignancy" means high intensity of the effect of the focus, in other words, hasty cell multiplication, great cell crowding, strong *vis-a-tergo,* rapid passive cell movement, correspondingly quick transportation of the cells, their short exposure to the influence of the focus and their rapid removal from the focal area of high chemical intensity to a less intensely effective part of the medium. If the exposure of the cell to the focus before it is being crowded off should have lasted less than two hours, it would appear not unreasonable to assume that the cell had undergone only that much of a change as to be in harmony with the less concentrated medium into which it was being pushed out, that the latter therefore can not enforce the continuance of the mitosis, started at the focus, in the direction toward malignancy. But if this same cell in its half divided state should later reach the extreme margin, there might then be here again sufficient disharmony between the partial malignant intoxication of the cell and the more or less normal marginal condition as to enforce the continuance of the interrupted mitosis; this time, however, in the direction of the detoxication of the cell toward normality. (See Böhm [13], quoted above.)

The same reasoning would perhaps also appear applicable to the observation of McConnell (27), also of Woglom (28) (p. 392), and "of most other pathologists" (Woglom), namely that "the most slowly proliferating tumors may contain a large number of cell division figures."—According to our contention, what looks like the growing edge of progressing malignancy might in reality be the receding edge of the tumor, in other words, the place where malignant cells, by undergoing mitosis, are being partially or totally deprived of their malignant properties, as Petersen and also Gaylord and Clowes observed, and where at the same time the medium thereby acquires a partially malignant intoxication which forces the fixed tissue cells there present also into mitosis, so that in summa a margin would have the appearance of a very busy progressive growth, when in reality a considerable part of it would be recession. This point of view seems to find further support in the observation of Woglom (28) (l.c.) that "a rapidly disappearing tumor may actually have more mitoses than a vigorously growing one," and in the observation of Erdmann (29) (p. 341) regarding in vitro conditions, that "a tumor cell remains a tumor cell only while it is being propagated in tumor plasma, otherwise it becomes a cell which shows by its behavior in subsequent reïmplantation that it approaches the state of a normal metazoic cell." Sokoloff (30) (p. 465): "Where cancer cells growing *in vitro* are studied . . . after the second or third transplantation . . . they lose their high activity and return to their ordinary relatively inactive condition. The reaction is the reverse of the original one which altered their nature. An alteration in external conditions . . . leads the growing cells to return gradually to their normal condition." Applied to our case the last two references would seem to say: A malignant cell transferred from the focus to the margin of the growth becomes at the margin changed back into a near normal cell.

On the basis of the foregoing discussion the statement would seem to appear not unjustified, that there is in the literature evidence which supports our theses of enforced cell division and passive growth, the latter being the sequel of the former.

Having considered the local effects and the near-distance effects of the (still assumed) focus, we can now proceed to the consideration of its far distance effects. As a preliminary thereto we have to examine first into the question of the dissemination of cancer cells.

The channels of cancer cell dissemination are the lymph vessels and the bloodvessels. At the outset we are therefore met with the question: if, as we claim, the cancer cells are moving passively in the tissue and are in fact possessed only of borrowed, imparted energy, whence then comes to them the energy that enables them to pass from outward to inward through the solid walls of the circulatory channels and to gain access to the inside of lymph vessels and bloodvessels? But, are these walls really solid? We shall note here some anatomical facts observed by means of vascular injection by Goldmann (24) (p. 3 ff.). Goldmann states: 1, that there are no lymph vessels in the walls of bloodvessels; 2, that the walls of lymph vessels and of arteries have vasa nutritia only in the superficial coat of the adventitia; 3, that in the walls of veins the vasa vasorum penetrate in treelike formation to the intima.—This anatomical condition would seem to make apparent why cancer cells gain access more readily to veins, than to arteries. Probably they are pushed forward along the outside of the small nutrient arteries in the venous wall, until they reach the intima. Here they would then be held up until they had set up an inflammatory process in the intima which would weaken the latter and make it give way before the *vis-a-tergo* behind the cancer cells, similar to the way Goldmann (l.c.) describes their gaining access to arteries, as follows: In the perivascular tissue of arteries and lymph vessels the cancer cells may be tightly jammed and nevertheless leave these vessels intact; only when influences, probably eman-

ating from these accumulated cancer cells themselves, have set up in the walls of the arteries and lymph vessels inflammatory processes, or when such processes arise from the thickening of the intima of the vessels, or from other disturbances of the structure of the wall, and when the capillary proliferation induced by these pathological conditions has weakened the texture of the closely knit walls, only then do the latter give way before the pressure of the perivascularly accumulated cancer cells. These then seem to find their way into the vessels along the outside of the newly formed capillaries in the walls of the vessels. In the bones the bloodvessels of the bone marrow are the gate of entrance for the cancer cells, according to Goldmann (24) (p. 15), and he lets bone metastases begin in the spongiosa, respectively in the marrow and appear only secondarily on the surface of the bones. Hence here, too, the *vis-a-tergo* behind the cancer cells would appear to be a sufficient explanation for what takes place.

From these directions, therefore, our argument would probably have to fear no objections and we would seem to be on passably firm ground when we assume that cancer cells are able to gain access to circulatory channels and bones on being merely passively propelled.

For the dissemination of cancer cells would seem to be of importance only their entrance into lymph vessels and veins, by both of which they are being carried to the right heart and the lungs. Cancer cells have been observed by M. B. Schmidt (7) to pass directly from the arterial to the venous capillaries of the pulmonary circulation. Once there, the entire systemic circulation is open to them. Schiedat (50) (p. 24): "The fact is definitely and firmly established that cancer cells can pass through the lungs into the systemic circulation."

(To be concluded)

The Causation of Malignant Neoplasms

JULIAN LOUDON, B.A., M.B., M.R.C.S., F.A.C.P.
JAMES M. McCORMACK, M.D., C.M.
and NORMAN J. HOWARD, Bacteriologist
Toronto, Canada

Many centuries have come and gone since the causation of cancer first engaged the attention of the medical profession. At the present time because of the alarming degree to which the ravages of this dread disease have increased and for the reason that it is likely that prevention and cure can be accomplished only through the discovery of the cause, the demand is importunate that we exert all our energies to disentangle the skein of uncertainties which obscure and confuse this problem.

Countless explanations and theories have been advanced from time to time. What we now require are unquestionable facts which will establish the truth.

Two main schools of thought continue to exist, viz., 1, that which adopts the cellular theory and says that all neoplasms are autogenous in origin and consist solely of an abnormal overgrowth of the cells of the person or animal concerned, and 2, that which holds that the proliferation of neoplastic cells is due to the presence of intracellular microorganisms.

A long paper might be written on the arguments advanced by each of these schools, but in this communication we shall confine our remarks to a brief description of the observations and researches of Glover (1), Scott (2), and ourselves (3).

These investigations have been made with the object of throwing light on the causation of cancer regardless of what the explanation might be, but they have ultimately led us to the conclusion that the cause lies in the action of an extrinsic living agent rather than in an alteration in the physiological laws of growth.

MORPHOLOGY OF THE CANCER MICROORGANISM

Following the method of Glover, strictly avoiding the employment of all cancerous tissue showing any evidence of necrosis or ulceration, and using rigid aseptic precautions and proper controls throughout the work, we have been able to isolate a morphologically similar microorganism from every type of malignant growth with which we worked, including human carcinoma, mouse carcinoma (63), rat carcinoma, human sarcoma, rat sarcoma (Jensen) and Rous chicken sarcoma No. 1. It has been possible to cultivate this same microorganism from the blood of the hosts of these malignant growths.

The life cycle of this organism is decidedly peculiar and consists of three separate and distinct microscopically visible stages, viz., 1, bacillus; 2, spore or coccus, and 3, spore sac, in addition to which there is what we have previously described as the filtrable or ultramicroscopic phase. Each of these microscopically visible individual stages can be grown in pure culture, but alterations in the composition or in the reaction of the culture medium or in its environment will cause one stage to pass into another in the above order or the reverse.

In addition to the metamorphosis from stage to stage, variations or lesser degree occur in each individual stage. For example, spore sacs exhibit variations in size and shape, and may or may not be associated with hyphæ. Cocci are spherical and comparatively small when passing to and from the spore sacs, but are ovoid and larger (the socalled spores) when giving rise to bacilli. Bacilli are small and thin when young, but become longer and thicker when older and containing spores.

The organism, in fresh cultures, is gram positive; it takes most of the ordinary stains but the bacillus and the coccus stages take the stains more readily than does the spore sac stage.

A striking feature of the life cycle of this micro-

organism is that it is filtrable in at least one of its phases. This is shown in either of the following tests:

1. A fluid culture of the actively growing microorganisms in either the bacillus or the coccus stage is first passed through a Buchner filter, in which pressed pulp one half inch in thickness and sand have been placed, to rid it of all the larger solid particles. The Buchner filtrate is then passed under pressure through a Berkefeld filter which before and after the experiment was found to hold back the Bacillus prodigiosus. A portion of the second filtrate is then taken up by means of a pipette and placed in the medium and incubated at 37° C. Within seventy-two hours pure cultures of bacilli or cocci, which show all the characteristics of the microorganism of the original fluid culture, are found to be present. Controls are invariably negative.

2. Pieces of fresh human carcinomatous, mouse carcinomatous, rat carcinomatous, human sarcomatous, rat sarcomatous and Rous chicken No. 1 sarcomatous tissues are taken and each tissue divided into two parts. One part of each of these tissues is placed separately in the medium and incubated at 37° C. The other part of each tissue is minced separately with sharp scissors and thoroughly ground with sand in a porcelain mortar in order to break up the cells; Ringer's solution is then added until the mass is well diluted and it is then thoroughly mixed. The suspension from each is next filtered and allowed to gravitate through layers of pressed pulp and sand to remove the sand and crushed tumor cells. The filtrate from each is then passed under pressure through Berkefeld filters which before and after the experiment were found to hold back the bacillus prodigiosus. The second filtrate from each cancerous tissue is then taken up by means of a pipette and placed separately in the medium and incubated at 37° C. After one to three days a pure culture is obtained from each of the various filtrates which is identical with that cultivated directly from the corresponding part of the same cancerous tissue; and in every instance the organism of each of these pure cultures shows the characteristics of the cancer microorganism described herein.

When each of the Berkefeld filtrates described in the foregoing experiment is centrifuged for one hour at 2,800 revolutions a minute and fresh and stained preparations made therefrom no organism can be observed under the ordinary microscope; but when these same filtrates are placed separately in the culture medium and incubated at 37° C. a pure culture is obtained from each of the various filtrates in from twenty-four to seventy-two hours which shows all the characteristics of the microorganism cultivated directly from the other portion of the fresh cancerous tissue. Controls are invariably negative.

BIOCHEMICAL REACTIONS OF THE HUMAN CARCINOMA MICROORGANISM

Gelatin, after being inoculated with stab cultures of the microorganism, is completely liquefied in from three to five days at room temperature. All sugars of a series with which we worked, excepting granatose, are fermented within two days at 37° C. The amount of fermentation and the increase in acidity of the sugar broth, and the degree of liquefaction of gelatin depend, however, upon the virulence of the culture; where the organism is attenuated by keeping it for some time under conditions unfavorable to its growth, or by subculturing it on media other than Glover's, it loses more or less of these specific properties varying directly with the degree of attenuation.

When the organism is grown in the fluid medium the acidity of the medium is at first increased due to the splitting of the sugar present in the medium; but after all the sugar has been used and as the production of the toxin reaches its maximum the reaction of the medium becomes alkaline. We believe that the action of the organism on the sugar in the fluid medium is similar to that which occurs in the living tissues when the organism invades a cell, i. e., it acts on the cell sugars, splitting them and causing an excess of acid at the same time liberating weak toxins. It is to these complex chemical substances or toxins that we must attribute the abnormal cell proliferation in carcinoma and in sarcoma.

PLEOMORPHISM OF THE CANCER MICROORGANISM

For the benefit of those who deny the possibility of such a complex life cycle as the one we have described in the cancer microorganism we suggest the perusal of the monumental work of F. Löhnis (4). In this work a changing of the morphology of microorganisms is shown to be a common occurrence, and variations in form analogous to those described by us will be seen to be present in the life cycle of several varieties of microorganisms. The pleomorphism of other microorganisms is brought out in the works of Francis (5), Tunnicliff (6), Parker (7), Räth (8), and Tunnicliff and Jackson (9).

Whether symbiosis accounts for such unlike types of the microorganism we describe has been carefully considered, but the fact that each type may be grown in pure culture and passed at will into pure cultures of the other types effectually disposes of any such theory.

Again the possibility of contamination by extraneous microorganisms can be dismissed when one considers the countless numbers of cultures and subcultures that have been made with the same result; and the experimental production of malignant growths with injections of this pleomorphic organism and the failure to produce malignant growths where experimentally contaminated cultures of the microorganism were employed.

Confirmation, in a greater or lesser degree, of the work herein described may be obtained in the papers of Young of Edinburgh (10), and of Stearn, Sturdivant and Stearn of Pasadena (11), each of which describes a pleomorphic microorganism isolated from carcinomatous tissues and having salient features in common with the cancer microorganism herein described. The micrococcus isolated from carcinomatous tissues by Nuzum of Chicago (12), and the ultramicroscopic organism isolated from sarcomatous tissues by Gye (13) and Barnard (14) represent, in all probability, individual stages or phases in the life cycle of the cancer microorganism herein described.

EXPERIMENTAL PRODUCTION OF CANCER IN ANIMALS

Glover demonstrated malignant metastasizing animal lesions, both in the gross specimens in living and in dead animals and the microscopic sections of same, at St. Michael's Hospital, Toronto, in June, 1920;

he demonstrated others at St. James Hospital, Butte, Montana, in June, 1924, all of which he had produced by repeated injections of pure subcultures of the cancer microorganism herein described. In an article in *Northwest Medicine* for April, 1925, Scott reproduces photographs and microphotographs of primary and secondary carcinomatous lesions produced by him in monkeys by means of repeated injections of pure subcultures of the carcinoma microorganism. From these lesions, both primary and secondary, the organism was again isolated and grown in pure culture.

IMMUNITY AND TREATMENT

The establishment of an immunity to cancer in animals is described by Scott in an article published in *Northwest Medicine* for April, 1925. In the October issue of the same journal Scott reports on results he has obtained in the use of an antitoxin, obtained through the horse, in the treatment of cancerous patients and refers again to the immunity now being produced in animals and in humans.

GYE'S SPECIFIC FACTOR

We produced Gye's "specific factor" in the manner detailed by him only substituted one half cubic centimetre of chloroform and treatment for a total of three and one half hours at 40° C., in lieu of the few drops of chloroform and treatment for a total of three hours at 37° C. specified by Gye (13). From this "accessory chemical factor" or "adjuvant" which Gye terms the "specific factor" in cancer we cultivated the cancer microorganism herein described in pure culture but in an attenuated form; when this microorganism cultivated from Gye's specific factor is injected with a trace of infusorial earth into the breast muscle of a chicken a true spindle celled sarcoma develops at the point of inoculation.

CONCLUSIONS

1. We have isolated a similar pleomorphic microorganism from every type of malignant growth with which we worked including human carcinoma, mouse carcinoma (63), rat carcinoma, human sarcoma, rat sarcoma (Jensen), and Rous chicken sarcoma No. 1.

2. The life cycle of this pleomorphic microorganism consists of three microscopically visible stages and of an ultramicroscopic or filtrable phase. Each of these microscopically visible stages can be grown in pure cultures and subcultures and at will changed into pure cultures of another stage in its life cycle.

3. Injections of this microorganism into animals, with a trace of infusorial earth, produces malignant metastasizing growths.

4. The microorganism can again be recovered in pure culture from these primary and secondary animal growths.

5. The pleomorphic organism described by Young and by Stearn, Sturdivant and Stearn appears to be similar to the microorganism herein described. The micrococcus isolated by Nuzum of Chicago from carcinomatous tissues and the ultramicroscopic organism described by Gye and Barnard appear to be individual stages in the life cycle of this microorganism.

6. The specific factor of Gye contains the living specific microorganism described herein, though the organism has been attenuated by the chloroform treatment.

7. Human carcinoma has been effectively treated by a serum antitoxin.

Gastric Ulcer and the Atomic Theory of Disease

With Observations on Diagnosis and Treatment

ELLICE McDONALD, M.D.
and ANDREW GODFREY, M.D.
Philadelphia

The surgical treatment of gastric and duodenal ulcer is reasonably successful at the expense of a major surgical operation, but there remains a certain percentage of these cases in which the operation does not complete the cure, and a certain percentage of recurrence of the disease after the operation. This recurrence is variously estimated at from five to twenty per cent. When, in addition, it is considered that laparotomy for gastric ulcer has a definite mortality, it is realized that operations of the type of gastroenterostomy (which do not directly treat the ulcer, but produce bodily conditions for its cure) do not offer complete satisfaction and are unintelligent measures at least as the mechanism of cure is imperfectly understood.

Smithies (1) has analyzed 566 cases of gastric cancer and believes that 77.5 per cent. had a history of gastric ulcer. This is suggestive that the treatment of gastric ulcer requires more careful consideration. This tendency to cancerous involvement seems to be limited to the prepyloric, as Orator (2) found malignancy in two per cent. of the ulcers of the middle portion, in thirty per cent. of the prepyloric region, but never in a duodenal ulcer in seven hundred ulcer and one hundred and fifty gastric cancer cases.

Cause	*Mechanism*	*Expression*
Energy from orientation and configuration of electrons in atoms and molecules.	Coalescence of colloid Bivalent and trivalent cations and anions produce vagus effects.	
Inorganic salts.	Less cell conductivity. Less potential difference. Anodal. Negative. Increased smooth muscle reaction. Lower pH (higher H-ion concentration in blood). Less permeable cell membrane. Vagus. Plasma less alkaline. Oxidation.	Most infections. Colitis. Typhoid. Diabetes. Neurasthenia.
Lipoid solvents.		HEALTH
Hydrogen ion concentration.	Reduction. Plasma more alkaline. Sympathetic. More permeable cell membrane. Higher pH (lower H ion concentration in blood). Decreased smooth muscle reaction. Positive. Cathodal. Greater potential difference. Greater cell conductivity. Univalent cations produce sympathetic effect. Dispersion of colloid.	Psychasthenia. Deficiency disorders. Tetany. Rickets. Syphilis. Eclampsia. Respiratory infections (tuberculosis) (pneumonia) Gastric ulcer Essential hypertension. Edema.
Oxidation reduction poise.		

METABOLISM

In a study of gastric ulcer cases by means of the fluoroscope, x ray pictures and estimation of acid base conditions (particularly in regard to the p.H. of the blood plasma) according to the method described by Ludlum and McDonald (3), it was found that the gastric ulcer cases were usually upon the alkaline, sympathetic side of the balance as shown in the accompanying diagram.

The method of study was by means of the ordinary clinical investigation of gastric ulcer, but in addition, the determination of the acid base balance (particularly blood plasma p.H.) and by complete x ray study, not only of the stomach, but of the large intestine. This resulted in the appreciation that gastric and duodenal ulcer is not a disease of acidosis, but usually a disease of alkalosis, with an alkaline p.H. in the blood plasma and that the stomach and large intestine showed evidences of sympathetic innervation as described by Ludlum and McDonald (3).

FIG. 1.—Normal colon, postural tone and haustral arrangement. These illustrations are made from thin paper tracings of the x ray films on the viewing box, so are correct as to scale and outline. The postural arrangement is dependent upon the vagus and sympathetic balance of the vegetative nervous system as is shown by our experiments with the injection of atropine (a sympathetic stimulant) and eserine (a vagus stimulant) with corresponding alteration in the colon and stomach picture (Ludlum and McDonald, "The Large Intestine and the Effects of Atropin and Eserine"—MEDICAL JOURNAL AND RECORD, 1926, Jan.). The postural tone and haustral arrangement are not, therefore, the result of socalled filling effects.

In the x ray study of gastric ulcer much attention has been given toward the questions of anatomical distortion, the degree of motility and retention of the barium meal, but little consideration has been given to the postural tone of the smooth muscle of the stomach and intestines and the reasons for these organs assuming the shapes they do. Essentially, motility of the stomach and intestines depends upon the balance of action of the vegetative nervous system. The vagus part causes contraction of the lower two thirds of the stomach and the intestines and the sympathetic portion causes dilatation. The upper or cardiac third of the stomach is in some dispute as to its innervation and, in our opinion, this possibly has three innervations, being both stimulated and inhibited by the vagus and inhibited by the sympathetic branches of the vegetative nervous system.

The character of the postural tone (haustral arrangement) of the gastric ulcer cases, was consistently uniform when x rayed under the condition of the test (twenty hour barium and in the absence of drugs, purgatives, menstruation or other conditions modifying the vegetative nerve balance). The haustra of the stomach were in large, sweeping, semiglobular movements (Figs. 2, 3, and 4) which we have learned to associate with sympathetic preponderance. The influence of the sympathetic is suffi-

cient to reduce the smaller active movements of vagus influence, but not great enough to completely inhibit the stomach movements. This type of peristalsis of the stomach, as viewed by the fluoroscope, was constant in our cases.

The postural tone of the large intestine, after the twenty hour barium meal, showed large, wide haustra which we have learned to associate with sympathetic preponderance (Figs. 2 and 4) which may be compared with the normal colon innervation of Fig. 1. This type of haustration was also constant in the gastric and duodenal ulcer cases, and has proved of some value in the differential diagnosis. This type of postural tone also is shown in other sympathetic preponderance conditions as tetany, pregnancy with edema, deficiency disorders, essential hypertension, etc., but its presence with a history of stomach disturbance is suggestive of gastric ulcer and its absence is suggestive that the diagnosis should be other than gastric or duodenal ulcer.

The hydrogen ion concentration of the blood plasma in our cases of gastric and duodenal ulcer was constant upon the alkaline side of p.H.=7.40. (The p.H. was taken after the method of Hastings and Sendroy, Jr., with bicolor standards.) In other words, instead of an acidosis, there was usually an alkalosis in our cases. There have been very few reported studies of the blood plasma p.H. in gastric ulcer.

FIG. 2.—a, b, c, d, e. Gastric ulcer case with typical gastric ulcer history for twelve years, vomiting, pain, occult blood in the stool. The hypotonus (sympathetic preponderance) of the stomach and intestine is shown. The blood plasma p.H. was 7.60. After treatment this p.H. changed to 7.35. This man had considerable emaciation and gained approximately thirty pounds under the treatment. He was able to resume his rather laborious occupation of house builder within eight weeks.

It must be recognized that titrometric methods of measuring the gastric acidity and total acids may give inaccurate results as to the intensity of acidity in stomach conditions. In a study of the p.H. in gastric ulcer, Kauftheil and Porges (4) found subnormal or normal values in ulcer of the stomach, but in duodenal ulcer there was frequently an increase in stomach acids. In 157 cases studied by Pletnew he showed that gastric and duodenal ulcer often developed with a low acidity of the secretion.

In our study we found that the gastric and duodenal ulcer cases had usually an alkaline p.H. and sympathetic preponderance. On the basis of the atomic theory of disease (5), they would then have increased cell permeability and increased conductivity. They would be deficient in the substances which produce decreased permeability (chiefly calcium and magnesium). They would have an excess of the substances which produce increased permeability (chiefly sodium and potassium). Their blood balance would be upon the alkaline side and they require the acid producing substances (like calcium and magnesium).

For this reason the gastric ulcer cases were treated by the administration of calicum lactate and Collip's parathyroid extract, and by the Jarotsky-Coleman (6) diet of white of egg, butter, etc. In fact we have come to allow in the diet all vitamine A substances. We have endeavored to have the diet salt free (sodium free).

The basis of this medication was from the following belief, 1, that calcium promotes protoplasmic rigidity and its absence, ulceration in epithelial tissues; 2, that calcium salts produce acidity (lessened alkalinity of the blood plasma; 3, that Collip's parathyroid extract has been proved to aid calcium metabolism and will increase the blood calcium content.

In regard to calcium and protoplasmic rigidity, Salm Horstmar (7) in 1856 first proved that calcium was necessary to plants. Ringer (8), in 1883, showed that if the calcium was extracted from the water, that the epithelial and mucous cells became detached from the gills of fish and that worms in calcium free water disintegrated. In experiments upon the sea urchin larvæ, Herbst (9) found that in sea water from which the calcium was lacking, the epithelial tissues dissolved into their component cells. When these dissociated, but still living, elements were returned to calcium containing sea water, they reassembled and adhered to each other at their point of contact. In plants calcium exists in the middle lamellæ and in its absence some plants will disintegrate.

Calcium is, therefore, apparently necessary to the continuation of complete organization of the cell and, in its absence the cells, particularly epithelial cells, will disintegrate. The calcium is thought to exist in the confining membrane of the cell, and so be necessary to the framework of the cell.

In regard to the production of acidity, it is commonly thought that calcium, being an alkali, will produce alkaline conditions in the human body, but this is not so, as it has been abundantly proved by Salvesen, Hastings and McIntosh, Haldane, Hill and Luck, Gamble, Blackfan and Hamilton, Ludlum and McDonald and Keith Barrier and Whelan (10 to 14) that calcium salts injected or ingested into the body will alter the hydrogen ion concentration of the blood plasma toward the acid side (or decreased p.H.). The reason of this apparently lies in the fact that the

human body organization is not a simple chemical system with a simple dividing chemical point at neutrality (p.H.=7.0) between acid and base, but is a collection of colloid cells, surrounded by semipermeable membranes in an aqueous medium and, in consideration of acid base conditions, the colloid constitution and surface action of colloids must be considered. The human body is a polyphasic colloidal system so that organization or mechanism enters into its chemical reactions and surface action, alteration in the structure of the colloid (dispersion or coalescence), adsorption and disorption and the electrical double layer of Helmholtz in the surface film must enter into consideration. For vital activities cannot be explained upon a stoichiometric (or purely chemical) basis, but must be translated in terms of colloidal chemistry which is essentially chemistry of organization and balanced relation at surfaces. The human cell exists as an acid colloid particle surrounded by a semipermeable membrane in a more alkaline medium and the dividing point between acidity and alkalinity for this system is not neutrality (p.H. 7.0) but somewhere on the alkaline side of this, as the univalent cations (sodium and potassium) produce alkalinity and the bivalent cations (calcium and magnesium) produce acidity. In other words, in studies of the acid base conditions, colloid structure as well as chemical reaction must be considered and this neglect is one of the fundamental fallacies of acid base studies of the crushed whole blood (cell and plasma) as in the alkali reserve estimations. As we found in our gastric ulcer cases a predominant alkaline p.H. of the blood plasma, calcium salts (conveniently the lactate) seemed very appropriate and were used. The use of this calcium salt usually altered the p.H. toward the acid side. In addition, Grove and Vines (15) have reported good results in the use of calcium and parathyroid in chronic skin ulcers.

The parathyroid extract was given because it has been proved that parathyroid extracts preside over and are associated with calcium metabolism, and Collip has developed an improved parathyroid extract which has definite advantages and has been standardized in units according to its capacity to increase the total blood serum calcium in normal dogs. We had the good fortune to obtain this extract while it was in the experimental stage, for which we thank Dr. Collip and the makers.

The treatment of these gastric ulcer patients, then, consisted in the use of the Jarotzki-Coleman diet, the administration of calcium lactate in doses of fifteen to thirty grains thrice daily, and the administration of parathyroid extract one tenth grain thrice daily by the mouth and the intramuscular injection every second or third day of two units of Collip's parathyroid extract. In markedly alkalosed cases with a high plasma p.H. dilute hydrochloric acid or dilute phosphoric acid was given in addition.

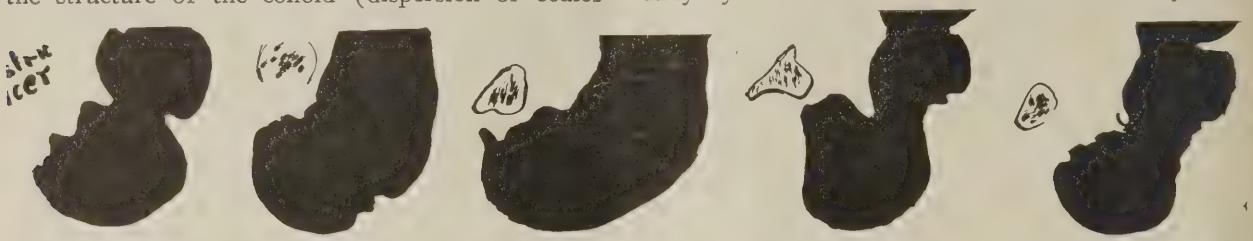

FIG. 3.—Gastric ulcer with typical history and occult blood. The patient made a good recovery within six weeks and occult blood has remained absent from her stools.

Under this treatment the patients gained in weight and improved in appearance. The occult blood in the stools disappeared in from four to six weeks which was taken as an indication of healing of the ulceration. The treatment was also used as a preliminary to operation with a view of aiding healing of the wound and also in certain cases after gastroenterostomy where occult blood persisted in the stool for some time after operation. The occult blood in these postoperative cases has disappeared under this treatment. Good results have been obtained in several cases of acute hemorrhage from gastric or duodenal ulcer by injection into the vein of 0.5 gm. of calcium chloride in 10 c.c. of distilled water, along with Collip's parathyroid extract hypodermically.

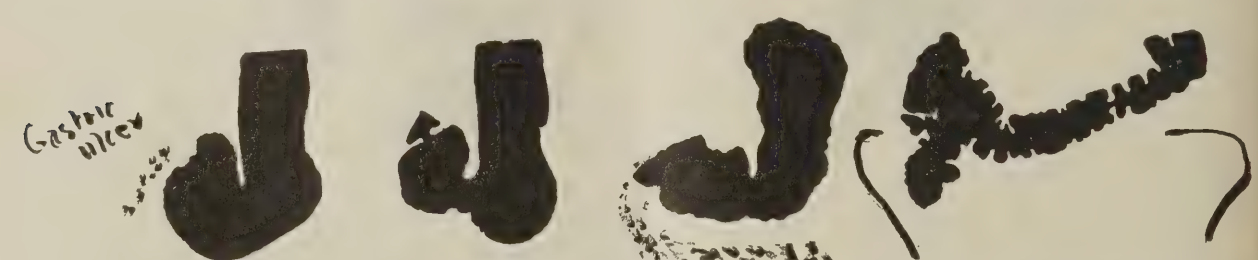

FIG. 4.—Gastric ulcer with typical history, vomiting, pain, loss of twenty pounds in weight; ninety-five pounds in weight, and occult blood. The postural tone and haustral arrangement shows the sympathetic preponderance. This patient had immediate improvement with a gain of thirty-five pounds in weight. The occult blood disappeared in five weeks and she has remained well for eight months.

The results of this treatment have been so satisfactory in gastric ulcer that, in our opinion, operation should be confined to those cases of gastric ulcer which show marked anatomic deviation and obstruction, or in cases where peritoneal hemorrhage is a factor. All other cases should have a trial of the calcium lactate and Collip's parathyroid.

Since writing this article there has come to hand an interesting study of the alimentary canal after parathyroidectomy by Spadolini (*Arch. di fisiol.* 1924. *22.* 339). He finds that, after parathyroidectomy, the principal cells of the stomach and the epithelium of part of the wall of the small and large intestine show various degenerative changes down to total necrosis. These are frequently associated with congestion, hemorrhages and edema of the intestinal wall. This work brings additional confirmation of the value of the parathyroid extract.

The author's references will appear in his reprints.

Physiotherapy in Hospital Team Work

NORMAN E. TITUS, M.D.
New York

In selecting this title for my paper, it is my desire to bring out one of the greatest factors in the field of usefulness of physiotherapy. I want to show, if possible, how physiotherapy fits into regular hospital procedures and has established a place as a useful adjunct in general medical and surgical work.

GROWTH OF PHYSIOTHERAPY

Before the war the number of hospitals which gave any attention to physiotherapy could be counted on the fingers of one hand. When the government realized the responsibilities it was under, and the services that were due the wounded of the army and navy, it was not difficult for physiotherapy to show that there was a place for its functioning in order to attain better results in the treatment of patients in the government hospitals. At first the government was not very anxious to try out physiotherapy, but finally its worth became understood and the usefulness of its departments under the reconstruction services of the army and navy became more and more evident. In the army it was very difficult to convince the old time army surgeon that electricity and other physical measures could be of any real service, but due to the persistent efforts of the head of the Reconstruction Department in the Surgeon General's office and a few progressive surgeons in the navy, physiotherapy finally gained its recognition.

Since the war it has been functioning in the work of the Veterans' Bureau and now more and more hospitals are becoming interested in the line of work that is done by physiotherapy. The whole system of treatments is being studied with a view to eliminating the parts that could not stand critical inspection. Medical schools are at last taking it up and in the Bulletin of the American Medical Association published in October, 1925, there is an article on Physiotherapy in Medical Schools and Hospitals which shows that physiotherapy is being taught in many medical schools and that in September there were twenty-four hospitals which had departments of physiotherapy. Already the figures in this article are out of date because many hospitals have taken up the work since last October. Beekman Street Hospital in New York city, which has had a department of physiotherapy for the past year and a half, is now running at the rate of some sixty thousand treatments a year and has shown a steady growth from the time the department was first started. Industrial firms are becoming more interested in the possibilities of physiotherapy in the treatment of the industrial injured and the whole subject is gaining wider fields of action in a very steady manner.

DEFINITION

For the benefit of those who are not acquainted with the subject, it might be well to mention what physiotherapy covers. Physiotherapy is the name given to the treatment of conditions by nonmedical and nonsurgical procedures and using physical means to obtain the results desired. I do not mean to say that the results are always obtained, but the measures are used in an attempt to bring about the reactions that will be beneficial to the patient. The name itself was coined in the Surgeon General's office and is not as universally accepted now as it was some years ago. This is mainly because a number of nonmedical persons, in order to make money in a pseudoscientific way, have taken up the subject and call themselves physiotherapists, when really their knowledge is not sufficient to license them as masseurs. Last year the American Medical Association created a Council on Physical Therapy and it will not be long, I believe, before the name of this work will be universally adopted to be physical therapy.

METHODS OF PHYSICAL THERAPY

Undoubtedly the largest part of physiotherapy is treatment with electrical methods. Then we have the mechanical methods, massage, hydrotherapy and phototherapy, including the oldest form of treatment, heliotherapy. All these methods are used separately or together in an effort to induce an adequate reaction to the pathology when the body has been unable to respond as it should. Physiotherapy is and always has been composed of the following parts: Ninety-five per cent. ordinary common sense, when the condition is looked upon from a trained physician's viewpoint. Of the remaining five per cent., three per cent. may be called the understanding of the actual technic of giving treatments and the other two per cent. is a knowledge of what the physical forces can and cannot do.

RADIANT LIGHT

Heliotherapy is a subject that all trained medical men have a slight knowledge of and in this country it is not used as much as it is abroad. In considering this subject I would like to bring to your attention a statement made by Professor Leonard Hill last summer at an international congress in London, in which he said there is no difference in the quantity of ultraviolet light seven miles up in the air and at the seashore. This rather changes the view that heliotherapy can only be done in the higher Alps, because, as you know, ultraviolet light is the active principle of sunlight that we attempt to give our patients in this form of treatment. Phototherapy, the treatment with light, really includes heliotherapy and also the use of radiant light of the spectral kind that can be appreciated by the eye and radiant energy above and below the visible spectrum. The former is called ultraviolet light and the latter, infrared. I am not going into a lengthy discussion of the subject of physiotherapy because that would need one paper by itself. However, I wish to draw your attention to one fact and that is, that radiant energy has the ability to penetrate a certain distance into the skin and according to the laws of the conservation of energy, when any form of energy is stopped heat is produced. Therefore, with radiant light we have two

forms of heat, the actual heat given off by the incandescent bulb and also the heat that is formed within the tissue by the light being stopped therein. Consequently with light we can cause the formation of actual heat beneath the skin.

Only recently I was asked to inquire into a situation at a hospital in New York which made the staff feel that the light treatments as being given in the hospital were rather dangerous. I found that the patients were being treated with applicators containing electric light bulbs and that the entire portion treated and the hood containing the electric lights were being surrounded by heavy blankets to keep in the heat. This was worse than misdirected enthusiasm because the double heat, as one might call it, was so great that it even baked the enamel on the hood and severely burned the patients. All of you may have seen attempts made at light treatments in different hospitals where a basketlike affair was placed over a patient's foot with an electric light suspended from that, and the whole thing covered with bedclothes. This is decidedly the wrong way to use light in treatment. It is absolutely necessary that the air circulate under the applicator, whether it be a special light containing applicator or an ordinary cradle such as is used under bed clothes. Let me warn you all that should you "see the light," as one might say, and use phototherapy, you must not try to make the patient feel the maximum amount of heat; and also you must see that the part being treated is open to the air. In burn cases and badly infected areas, it is the custom at Beekman Street Hospital to throw a piece of mosquito netting over the whole apparatus so that the air can circulate and no flies and a minimal amount of dirt reach the part.

One more point before leaving phototherapy which most people do not realize. For years it has been a custom in different hospitals to expose indolent ulcers to sunlight and I myself have seen in many hospitals patients sitting with a wound exposed to the sunlight which is passing through a window to the part. The active principle of sunlight is ultraviolet light and ultraviolet rays will never pass through ordinary window glass. As an example of this fact, I do not think that anybody has ever noted that people get sunburned when sitting in sunparlors. Solariums as constructed today are nothing but overlighted rooms with no therapeutic value whatsoever.

HYDROTHERAPY

Hydrotherapy, which is a part of physiotherapy, is not being used as extensively today as it formerly was, especially during the lifetime of Dr. Baruch. It has its place in hospitals for chronic diseases, and especially where the patients are of the neuropsychiatric type. Nowadays the most useful form is the whirlpool bath where warm water is agitated by a stream of air passing through it. This is found to act as a very mild massage and is very sedative in the treatment of peripheral nerve injuries. It also is used in fractures where the union is almost complete, when it is desired to keep the skin and muscles in better condition than just letting them lie in a cast.

MECHANOTHERAPY

Mechanotherapy is still very extensively used in Europe, where there are all sorts of machines originated by an ingenious man named Zander. In this country, however, we feel that results obtained by these machines can be better brought about by the judicious use of exercise either given by or under the eye of a skillful physiotherapy technician.

MASSAGE

Massage has a definite place in general therapeutics. It is of such usefulness that had the older physicians not neglected its possibilities, we would not today have these trick cults flourishing throughout the country whose main idea is the possibly scientific application of massage.

THERMOTHERAPY

Thermotherapy is essentially the use of heat in the form of dry or moist air and its usefulness is not as great at present as heretofore, as radiant heat is far superior in most all cases.

ELECTRICITY

I will sketch briefly what can be expected with the use of electricity in treatments. We have available for therapy the old galvanic current, which is still best obtained from batteries; and variations of this current, such as the sinusoidal current and other wave currents of low voltage. The faradic current has a very limited field of usefulness and these two forms so far mentioned are used mostly for the stimulation of muscles that are in poor condition, or nerves that need stimulation. There is undoubtedly some chemical effect from the galvanic current which has a field of usefulness. We have two other currents, namely, the high frequency currents which are most popularly known today because of diathermy, and the static current which is the old current generated by friction and is peculiar in that it has extremely high voltage and practically no amperage or volume. The high frequency currents are used to generate heat by putting certain parts of the body as a resistance in the circuit. The static current is used for from very mild up to very powerful mechanical effects, and in a way it surpasses massage. It is the greatest means we have today to reduce congestion and infiltration in tissues.

I hope you can see from the sketchy outline of the subjects I have mentioned what forces physiotherapy can command that can be used for the benefit of the patient. It is not possible to enumerate all the conditions in which heat, mechanical exercise, or reflex reactions, such as can be brought about by use of these agents, can be of help. Standard medical and surgical procedures have been so studied and worked out in the years gone past that physiotherapy can never pose in any way as a competitor of such rational procedures. Any man who believes in the statements made by some of the fanatics, such as "the day of the knife is over" and all that, is not using his mental capacity as a physician.

Physiotherapy is undoubtedly the most modern and potent adjunct that has come into the field of therapeutics in many, many years. It has been able to make a place in the general hospital team work when conservatively prescribed so that the results that the surgeons and physicians desire to obtain, are frequently helped as to speed and perfection when physiotherapy is brought into play. I know of no condition, with the exception of superficial infections when treated with ultraviolet rays, in which physio-

therapy itself can assume the credit for bringing about a cure. It is not intended to be used actually to treat the condition as such, but, as I mentioned before in this paper, it is an attempt to change an inadequate reaction to the existing pathology into one that is adequate so that the patient *himself* gets well. Do not forget that it is ninety-five per cent. common sense and if it seems that a convalescence can be shortened, or resistance can be increased, or the reparative reaction of the patient can be whipped up to his advantage, then physiotherapy can be called on as a sort of "pinch hitter" to turn the tide into a more favorable direction.

Let me warn those who are thinking of taking up this subject, especially hospital men who feel that they should become the most modern in their treatment and encourage physiotherapy in their hospitals. Do not trust the prescribing of these measures to anyone but a physician. Note that I say physician as a medical graduate who has had special training in physiotherapy. The x ray man of a small hospital, because he has a knowledge of switches and currents, very frequently has the job wished onto him. That is very unfair to him and quite unfair to physiotherapy. With the courses that are available in recognized medical schools and hospitals today, men can be trained in six weeks or more to have a good working knowledge on the subject. These "get-smart-quick" courses that are foisted on the medical public by manufacturing concerns, where the entire subject can be "learned" in eight to sixteen hours of work in one week, cannot be recommended in any sense except as a slight introduction for a bowing acquaintance with the subject of physiotherapy.

It has been found advisable to leave the final word concerning the treatment of the patients to the medical man who is directing the department of physiotherapy. However, in order to encourage the other members of the staff to increase their knowledge of the subject, it is always acceptable to have them make out tentative prescriptions for treatments, but the entire responsibility for the treatments is on the shoulders of the director. The best cooperation between the department and the rest of the hospital staff is obtained by requiring the attendance of the director at the weekly field rounds which are the custom in all good hospitals. At that time the staff can ask questions regarding treatments and the director has an opportunity to see exactly what surgical treatments all the patients are getting.

One other point worth mentioning is that treatments cannot always be given personally by the doctors. The physiotherapy technician of today has an undisputed place of her own in this work, and should anyone think of enlisting the services of a technician, let me warn him to inquire fully into her training and experience. There are many socalled physiotherapists and technicians who know worse than nothing about the subject. The American Physiotherapy Association can always supply the best technicians.

I must admit that this paper is not of any scientific nature, but it is merely an effort on my part to bring to your attention the fact that decently understood and controlled physiotherapy is another tool in the tool box of the medical profession. It is worthy of more attention by the hospitals and the profession in general because it can so easily fit into the therapeutic team work and be a distinct aid to results that the physician and surgeon like to view with satisfaction.

Pernicious Anemia*

Report No. 3

LEONARD E. CROFT, M.D.
Los Angeles

At the last clinic held here August 11, 1925 (1) two men were shown whose symptom complex corresponded closely to that found in Addisonian Biemer anemia, which for many years has been designated as pernicious anemia. The subsequent course of those patients is as follows:

Case III.—(Record No. 5814)—This patient, at the time of presentation, was bedridden, and had a hemoglobin of twenty-seven per cent. and 900,000 erythrocytes, and a color index greater than 1. He was given mercurochrome intravenously (2) (twenty cc. of one per cent. solution) three times but continued to grow weaker and died on October 2, 1925. At autopsy the liver was found to be two finger breadths below the costal margin; the gallbladder markedly distended and would not empty by pressure. The bile was dark and thick and the walls of the gallbladder slightly thickened the common duct. The duodenum and lower portion of the liver were involved in a dense mass of adhesions which caused considerable constriction of the first portion of the duodenum, which explains some of his gastric symptoms, such as gastric retention and vomiting. As will be recalled, the clinical diagnosis in this case was scirrhous carcinoma of the stomach. The spleen was about one third larger than normal; the pancreas small and hard and coarsely granular. The tibia cortex was thin, the marrow cavity increased and filled with red marrow, which showed microscopically many megaloblasts, gigantoblasts, as well as primitive leucoblasts.

Case IV.—(Record No. 6806)—This patient, at the time shown, was in the beginning of a remission which lasted until about the first of November. From that date he went down in spite of treatment, which included four courses of mercurochrome intravenously (thirty c.c. of one per cent. solution), and died on December 26, 1925.

*From the Department of Internal Medicine, service of John W. Shuman, M.D., N.G.D.C.S. Read at a meeting of the Los Angeles County Medical Society (Santa Monica Branch).

The autopsy report was as follows: The areolar tissue was well preserved and markedly yellow in color. Spleen weighed 250 gms., two small infarcts, gallbladder not distended but contained three ounces of dark green thick viscid tenacious bile. Gallbladder mucosa had a fine granular feel; the stomach was thin walled, except in the pyloric end; the mucosa was atrophic as in atrophic gastritis. Bone marrow was yellow and fatty with no signs of redness about it. Just above the sigmoid region of the large intestine there was an area about six inches long of markedly thickened gut. Above this area the large intestine was greatly dilated and the walls were very thin. This specimen, together with the gallbladder, was submitted to Dr. Frank Sturdivant, pathologist to the Pasadena General Hospital for examination. He reported as follows:

"Spinal cord, no definite pathological changes noted. Gallbladder showed chronic cholecystitis. The microscopical findings of a chronic colitis, together with macroscopic findings of multiple diverticuli, are accountable for the constriction in the large bowel with dilatation and thinning of the walls above this point. While not often reported it is in my experience not uncommon. With the present views on pernicious anemia, one of the suspected contributing causes is an unknown infection involving the gallbladder and the intestines, especially the colon. These findings are in harmony with the clinical diagnosis of socalled pernicious anemia."

CONCLUSIONS

1. Our cases emphasize the importance of careful antemortem and postmortem study.
2. All our cases showed a pathological condition which could have caused grave pernicious anemia.

The Diagnosis and Treatment of Displacements of the Semilunar Cartilages

P. LE BRETON, M.D.
and R. M. CLEARY, M.D.
Buffalo, N. Y.

In making a survey of fifteen cases of removal of the cartilage of the knee joint during the past few years, we have interested ourselves in summarizing the important points in the diagnosis and operative technic, and have derived benefit from the study of this unique condition. This paper presents the conclusions obtained. The subject is always attractive as the lesions vary greatly. In no other part of the body do we find similar mechanical possibilities.

ETIOLOGY

In these cases the tear in the cartilage was due to injury while the knee was flexed and subjected to violence by rotation, as in rising from a kneeling position. Usually the cause was muscular effort, but in a few cases direct injury, such as a fall on the flexed knee, produced the usual condition. In one case, a mechanic kneeling before an automobile was struck on the knee by the axle of the car as it slid off a jack. In one case, typical as a tear of the anterior half, no history of any injury could be obtained. Flexion of the knee at the time of violence is regularly present. With rotation the tibia rotates outward and the femur inward. The cartilage is pinched between the bones so that a tear is started, loosening the more mobile anterior half or causing a split longitudinally, which resolves itself into one of the final forms. Two thirds of our cases were in males, as might be expected in any traumatic condition. All patients were adults, except one, a girl of fourteen, who fell directly on the flexed knee.

LESIONS

Conditions found on operating are shown in the illustrations. Except for the two cases in which the cartilages appeared normal, there were the following: one a loose anterior horn; one a loose tag from the anterior horn; two frayed at the inner edge; five longitudinal splits; and four bucket handles. In these bucket handles, the cartilage is first split; the inner half is dislocated to the middle of the joint, still attached at each end. It might be noted that in three of the bucket handle cases, the misplaced cartilage had been supposedly reduced by manipulation previously and yet at operation were found lying in the centre of the joint and had never been replaced. In two cases of unusual interest, it was the external cartilage that was loose at the posterior end. In each of these the injury was direct. In walking a marked click could be heard, and also felt when the knee was flexed. At operation, as the knee was moved, it was easy to demonstrate how the cartilage jumped forward with a snap in flexion, slipping back again between the two bones on extension.

SYMPTOMATOLOGY

As the diagnosis so often rests on the history, the subjective symptoms, and a negative x ray, rather than on objective signs in the knee itself, the story told by the patient is of prime importance. The nature of the injury, the description as to how the knee goes "out of place," or "catches" or "locks," must be gone into minutely. Also the reaction in the joint following each misplacement; the site of pain and tenderness; the frequency of misplacement, and the patient's own method of reduction. Locking, which is the most typical symptom, is by no means always present, and is often a temporary catch. Inability fully to extend the knee immediately after the injury indicates displaced cartilage and is the most positive sign. This symptom is usually absent in recurring attacks.

In the examination it is a good plan to watch the patient walk and stand with both legs bare. Limp, knee flexion, fluid in the joint and atrophy of the quadriceps can be readily observed. On having the patient bend both knees toward a squatting position, if he is willing, swelling, atrophy and limited motion become apparent. There is regularly present some atrophy of the quadriceps, and if the patient has been wearing a rubber knee cap for any length of time the atrophy may be extreme.

In the prone position, on palpation, the typical sign is sharply localized tenderness over the joint line one and a quarter inches to the inner side of the lower end of the patella. This point is over the internal cartilage in front of the internal lateral ligament. It is *the* typical point and was found sharply localized in four fifths of the cases. Motion is usually normal with no creaking, unless there is present a displaced cartilage, acute synovitis from a recent catch, a chronic arthritis from repeated insults, or some adhesions.

To rule out torn ligaments: With patient in prone position compare the two knees by testing normal knee first. With the knee completely extended, try to abduct. Absence of lateral chug indicates a firm lateral ligament. With the knee extended, try anteroposterior motions by gripping above and below knee. If absent, the anterior crucial is normal. In the sitting position with the knee flexed to a right angle, try forcibly anteroposterior motion with both hands clasping the upper calf. Firmness indicates a normal posterior crucial. While rotation in flexion is the force which catches and tears the internal lateral cartilage, it is well to remember that abduction is the force that tears the internal lateral ligament, hypertension tears the anterior crucial, and direct force in flexion tears the posterior crucial.

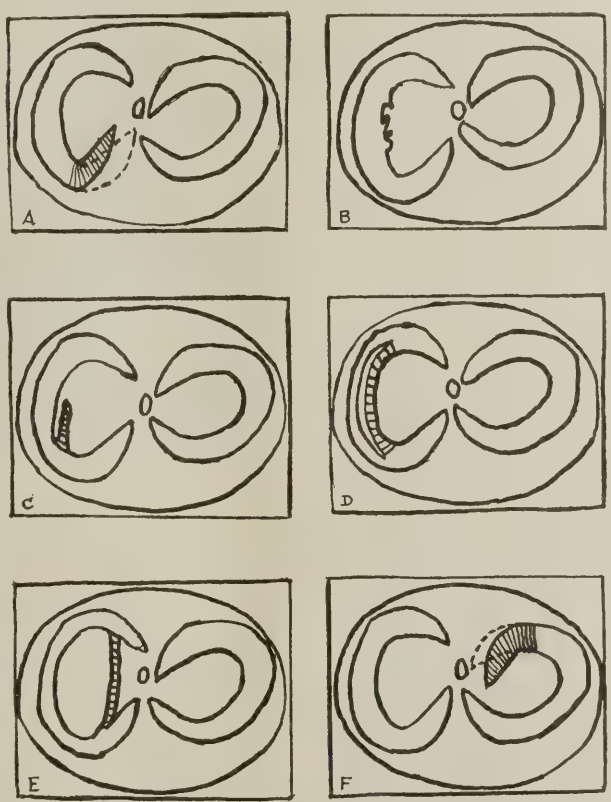

FIG. 1.—Showing the various conditions found in the knee joint upon operating.

DIAGNOSIS

In all of our cases the x rays were negative, and the negative x ray aids in diagnosis. Of course a coincident lesion is possible. The presence of loose bodies or an intraarticular fracture may change the diagnosis. Rarely an early tuberculosis may simulate a cartilage condition. Instability due to lax ligaments is found by testing and comparing the ligaments of both knees. In two of our cases showing lax ligaments, however, the history was positive and removal was followed by cure of the cartilage symptoms and general improvement in tone. Enlarged retropatellar fat pad may simulate, but the catch is slighter; there is creaking under the patella especially in forcible extension by the patient himself; and there is a distinct doughy thickening at the sides of the bone. Adhesions should show limited motion and irregular tenderness. Chronic arthritis should show the usual changes, such as swelling, limited motion, and x ray findings.

TREATMENT

In the case seen at once after the accident, with the patient walking on a flexed knee, the indication is to reduce the cartilage which blocks full extension. With the patient lying down on his back, the leg is gently flexed on the thigh to about forty-five degrees below full extension; then the leg is rotated inwards and abducted, by means of the hand and the knee of the operator. This opens the space for the cartilage to slip back and it works particularly well if the patient is under an anesthetic. If the patient is not under an anesthetic, ask him to kick out in extension while maintaining inward rotation. Easy complete extension usually means reduction but in bucket handle not necessarily.

Authorities differ on whether to splint for two or three weeks to give complete rest and healing or to allow weight bearing with the knee splinted in extension. Confinement gives the cartilage time to repair but may mean adhesions and atrophy which disable for some time. We have usually allowed weight bearing except in the marked case with first displacement. The use of a Thomas heel undoubtedly helps to maintain abduction and inward rotation of the leg on the thigh, guarding against recurrence.

In the latter case, with repeated displacements, the cure is effected by removal before chronic inflammation and lax ligaments cause permanent damage. Just here it must be emphasized strongly that such opening of the joint does not cause a "stiff" joint. This is the general impression among the laity, nurses, and physicians; that incision and removal of the joint fluid is followed by stiffness. In almost all cases lengthy arguments precede consent to operation.

The method of Sir Robert Jones is preferred. The preparation should be a thorough two day preparation and the strictest technic used to prevent infection, such as the use of instruments only in the wound, instead of fingers. The operator should have two assistants, good light, a tenotomy knife, and several blunt hooks in readiness. The tourniquet aids greatly

in keeping a dry field and prevents blood from collecting in the joint. The leg is wrapped in sterile bandages from toes to knee and the sheet caught firmly just above the knee, with a small area of skin exposed. The operator sits on a stool with the patient's foot in his lap. The usual curving incision is made about two and one half inches long, the capsule split, and the joint opened. By hook retraction, careful inspection is made to determine the condition of the cartilage, using a hook to lift the free inner edge. Redness of synovia due to irritation is often present. It is best to excise as much as possible, not only the affected part but the remainder which is adherent to the capsule. In doing this a small tenotomy knife is best or else Freiberg's modification. Rarely the posterior horn must be entirely removed, in which case a second incision may be necessary back of the lateral ligament. In one of our cases of external cartilage, in which the location of the click was uncertain, the patella was split longitudinally. The wound is closed in layers and a splint applied for ten days. Massage and gentle active movements are encouraged and the free use of the limb after three weeks, if healing has been normal.

It has been noted that a branch of the internal cutaneous nerve may get caught in the scar tissue causing local tenderness. One of our patients had this happen and the scar was excised under local anesthesia with good results.

The prognosis is, as a rule, excellent. If arthritis, joint irritation, or lax ligaments are present, a more guarded prognosis should be given.

CONCLUSIONS

1. In cases of displaced cartilage, the history of injury in flexion is of great importance, for the knee on examination may appear normal.
2. Lack of complete extension and the typical point of tenderness are characteristic symptoms.
3. It may be impossible to prophesy whether the cartilage will appear normal or not and on which side the trouble lies.
4. Lax ligaments are often encountered, and a history of catching or slipping due to such may simulate a cartilage condition.
5. The laity in general has to be informed that operation does not mean a stiff joint.
6. The aftertreatment should be followed up with considerable care.
7. The operation should be attempted under ideal conditions only.

40 North Street.

The Nonsurgical Constipations, Functional and Mechanical*

MAX ERDHEIM, M.D.
Brooklyn

Constipation, while one of the most common conditions, does not receive the degree of attention from the profession that it deserves. We are too likely to underestimate the importance to the patient of this complaint. Many of us treat the disturbance in a more or less routine manner, making no effort to discover the particular causative factors existing in the individual case. The unfortunate result of this neglect is that the patient, as a rule, wanders from doctor to doctor and finally resorts to quacks.

In this paper I shall show that every case of constipation presents a definite clinical problem, that widely diverse factors may cause the condition, and that no examination is complete until a thorough study has been made to determine the possible mechanical and physiological causes operative.

The subject of the mechanical constipations is a broad one and, since the advent of röntgenology, much has been written in this field. The functional constipations, on the other hand, have not received such careful consideration. Their common classification into tonic and atonic groups is not consistent with recorded observations and with the present day views of the physiology of the gastrointestinal tube. It is for this reason that I am urging a classification of the functional constipations based upon the established tenets of physiology. I am using the word constipations in the plural advisedly, in order to indicate that these conditions may be associated with diverse types of underlying disturbance.

*Read before the Eclectic Medical Society of Greater New York, November 10, 1925.

INNERVATION OF THE INTESTINE

The comprehension of the functional constipations presupposes a knowledge of the innervation of the intestine and of the two antagonistic systems of extrinsic nerve fibres, namely, the sympathetic and the parasympathetic nerves. The theory of sympathetic-parasympathetic antagonism enunciated by Eppinger and Hess (1) is one of the basic ideas underlying the study of the functional constipations. The vagus, the principal component of the parasympathetic system, is the motor nerve of the stomach and intestines. It is directly antagonistic to the sympathetic fibres coming by way of the splanchnic nerves, whose function is to inhibit the movements of the stomach and intestine. The nerve fibres mentioned above pierce the wall of the gut and terminate around the plexuses of Auerbach and Meissner. In addition to these fibres, others derived from the vagus nerve form plexuses on the serosa of the intestine; from these plexuses fibres pass directly to the muscular layer of the gut, that is, independently of the Auerbach plexuses.

The plexuses of Auerbach and Meissner are the relay stations through which the extrinsic nerve fibres, including the vagus and the splanchnic nerves, influence the movements of the gut. Auerbach's plexus lies between the circular and the longitudinal fibres of the muscular layer; Meissner's, in the substance of the muscularis mucosæ. The Auerbach plexuses are also of interest in that they are capable of performing some of the functions of the colon independently of the extrinsic nerve fibres.

By reason of its double innervation of the intestine,

the vagus, when stimulated, may produce either a peristaltic contraction or a spasm, depending upon which group of its fibres is being stimulated. If the portion of the vagus that reaches the Auerbach plexuses is irritated, a peristaltic contraction will result; whereas, if the fibres that go directly to the muscular layer are stimulated, a spasm will be produced.

FIG. 1.—The ascending type of constipation. A twenty-four hour barium plate. The barium has reached the end of the first portion of the transverse colon (neuromuscular ring of Keith). Note that the cecum is dilated and down in the pelvis, apparently held there by adhesions.

Peristalsis may result also from the independent action of the nervous structures located in Auerbach's plexus. For this purpose, it requires an exciting factor. The principal exciting factors of independent peristalsis, as mediated by the plexus of Auerbach, are as follows:

1. The normal contents of the bowels.
2. The hormone cholin, furnished by the intestinal walls. Zülzer (2) has prepared and described a peristaltic hormone, called neohormonal, which is derived by an extraction process from the mucous membrane of the stomach and the spleen of animals.
3. The hormones secreted by certain endocrine glands, principally the thyroid and the hypophysis.

Recalling the fact that the vagus and the sympathetic nerves to the gut are antagonistic, one can easily understand how disturbances of these two nervous units may produce a condition of functional constipation. When the sympathetic innervation of the gut is overactive, the motor nerve of the colon is inhibited and a hypokinetic type of constipation results. When the stimulation of the vagus fibres to the gut is excessive, peristalsis may be heightened to such a degree as to produce diarrhea, on the one hand, or localized spasms of the gut, on the other. This illustration should serve to show how either of two entirely different mechanisms may produce constipation, and how essential it is to differentiate these two types.

The functions and forms of motion of the colon may be described under the four following heads:

1. A mixed motion is to be found in the cecum, ascending colon and the first third of the transverse colon. A contracting ring, the neuromuscular ring of Keith, forms at the junction of the first with the middle third of the transverse colon, with the result that the contents of the cecum and ascending colon are prevented from being propelled further until decomposition, fermentation and resorption have been completed.

2. Peristalsis is characterized by a wave of contraction preceded by a wave of relaxation. This function is most powerful peripherad to the neuromuscular ring of Keith. A single wave may transport the colonic contents beyond the splenic flexure or even as far as the sigmoid.

3. Tonic contractions of the gut may take place in various segments, thus forming an obstacle to the forward propulsion of the contents. The contractions may last only a few minutes or as long as hours; they are most common at the distal end of the transverse colon and in the descending colon. Such misplaced and mistimed contractions may be responsible for the condition popularly called "cramps."

4. Defecation is a mechanical process operating independently of the functions enumerated above. Constipation may result from functional defects of the colon above the rectum, and, nevertheless, when the intestinal contents reach the rectum, they may be

FIG. 2.—The hypokinetic type of constipation. Forty-eight hour barium plate, no defecation. Note that the entire colon is filled.

expelled immediately. On the other hand, the rectum may take part in the production of a type of constipation known as dyschesia, which is usually a secondary manifestation, rarely a primary condition. The great factor in the production of dyschesia is the use of the rectal enema to relieve constipation arising elsewhere. As a rule, the contents of the rectum and sigmoid are

expelled in one movement. The daily act of defecation is largely regulated, under normal conditions, by the four functions enumerated.

FUNCTIONAL CONSTIPATION

By functional constipation is meant a condition that results not from mechanical abnormalities affecting the gut, but from a disturbance of the balance of the motor and inhibitory nerves. The terms tonic and atonic constipation are still commonly used, but physiologists have long since shown that the conditions that their names imply do not exist. The theory of muscular relaxation, which must necessarily enter into an explanation of constipation on an atonic basis, was discredited by physiologists over twenty years ago.

Fig. 3.—The dyskinetic type of constipation with dyschesia, due to abuse of enemas. Seventy-two hour barium plate. Note the spasm in the descending colon and the accumulation of barium in the ampulla.

About thirty-five years ago, Nothnagel denied the theory then in vogue that functional constipation was due to an inherent weakness of the muscular walls of the intestine. He defined this condition as an abnormal state of the nervous mechanism controlling the peristalsis of the colon and rectum, but declared the cause of the disturbance to be unknown. To Nothnagel belongs the credit for invalidating the misleading terms "tonic and atonic constipation."

Many subsequent experimental and anatomical investigations have since confirmed Nothnagel's theory. Adolph Schmidt made a last serious attempt to shake this theory by bringing forth an opposing one of his own. Schmidt advanced the hypothesis of a condition of hyperpepsia of the small intestine in functional constipation. He assumed that increased digestion and absorption from the small bowel leave an insufficient residue in the colon to initiate the act of defecation. But Schmidt's view is untenable, because the diminished quantity of waste matter in constipation is readily accounted for by increased absorption resulting from retention in the colon.

Gustav Schwarz (3) in 1912, as a result of his röntgenological studies, divided functional constipation into four types as follows:

1. The ascending type. In this type a constriction forms at the neuromuscular ring of Keith and interferes with the forward propulsion of the intestinal contents.

2. The hypokinetic type. This type involves the entire colon, producing sluggish bowel activity. It may result from a depression of the vagus or motor nerve or from an overactivity of the inhibitory splanchnic nerves, or from a depression of the Auerbach plexuses themselves.

3. The dyskinetic or spastic type. This form usually begins in the transverse colon and progresses peripherally. It is characterized by an interference with peristalsis due to spasm. The dyskinetic type of constipation results when the vagal fibres that go directly from the serosa to the muscular layer are overstimulated. Irritation of the vagal fibres that act via Auerbach's plexuses would produce diarrhea.

4. Dyschesia or rectal constipation. This type is readily recognized by rectal examination. A knowledge of the existence of the dyschesic type of constipation is important, inasmuch as the treatment of this type differs from that of the others. In dyschesia masses may accumulate for as long as three or

Fig. 4.—Asthenic patient with prolapsed colon who did not suffer from constipation. Twenty-four hour barium plate, with one bowel movement. Note that the hepatic flexure is at the level of the crest of the ilium and the splenic flexure is only slightly above this level. At forty-eight hours, the colon was empty.

four days before being expelled. The presence of such masses in the rectum, however, is not constant; in some cases the rectum will be found to be empty for as long as twenty-four hours after defecation.

ETIOLOGY OF FUNCTIONAL CONSTIPATION

Dietetic.—An insufficiency of roughage in the diet is most important. When the dietary is insufficient or does not contain enough indigestible residue, the normal peripheral stimulant to peristalsis is lacking. Because of the fact that their food was so much more refined, the upper social classes in Europe before the war were apt to suffer from this type of constipation. During the war, as was pointed out by von Noorden (4), this type of constipation disappeared.

Sedentary habits have often been given as an important cause of constipation, but the truth of the matter is that the eating habits of the sedentary person rather than his occupation cause the condition. This contention can easily be proved. Patients with fracture, necesarily confined to bed for weeks at a time, do not suffer from constipation when they receive a full mixed diet. However, if their dietary is reduced to soups, cereals, etc., they eventually become constipated.

Endocrine. — Conditions characterized by a diminution of the endocrine secretions that normally augment peristalsis may give rise to a hypokinetic form of constipation. Hypothyroidism and hypopituitarism come within this category.

States of worry and excitement, by stimulating the sympathetic nervous system, are capable of causing constipation of the hypokinetic type. Cannon (5) has emphasized the important part that the emotions may play in disturbing the balance of the nervous control of intestinal movements and function.

FIG. 5.—Same patient as in Fig. 4, after barium enema. The plate shows a redundant sigmoid; nevertheless, there was no constipation.

DEPRESSED EXCITABILITY OF THE PLEXUSES OF AUERBACH

The activity of the plexuses may be depressed by toxic causes, by nervous reflexes or by impulses from the central nervous system. Unquestionably, there may be a constitutional hypoexcitability of the nervous apparatus of the bowel. A breastfed baby or a young child whose bowels have not yet developed for cellulose digestion may be constipated.

ABNORMAL EXCITABILITY OF SYMPATHETIC NERVES

The excitability of the sympathetic nervous system, which inhibits intestinal movements, may be enhanced; or the vagus, on the other hand, may be unduly depressed. This syndrome produces a typical hypokinetic constipation. Nicotine may produce constipation by stimulating the sympathetic nervous system; morphine, by depression of both the vagus and its antagonist.

ABNORMAL EXCITABILITY OF VAGUS

An increased tone of the vagus nerve fibres may produce diarrhea, when the fibres that pass to the plexuses of Auerbach are overstimulated. On the other hand, if the irritative impulses are conveyed via the fibres that pass directly from the serosa to the muscular coat, spasmodic contractions will result. If the overactive vagal impulses were uniformly distributed throughout the colon, the natural result would be diarrhea; but the spasms are usually restricted to small segments of the bowel, with the result that peristalsis is impeded. The agents that are most likely to produce this type of constipation are psychic causes and such drugs as psysostigmine and pilocarpine. Hanneman (6) has adduced evidence to show that neurotic overexcitability is a primary factor in the production of dyskinetic constipation. He reports good results from psychotherapy in appropriate cases.

DYSCHESIA

Rectal constipation may result from a loss of the sensitiveness of the defecation reflex. This condition may ensue from a continued habit of suppressing the normal reflex, as a result of which the nerve endings in the rectum finally become insensitive to the normal impulse.

MECHANICAL CONSTIPATION

Mechanical causes may account for some types of constipation, but their importance has been greatly overemphasized. Lane has laid a great deal of stress upon the importance of kinks in the ptotic transverse colon as the cause of constipation. His views have not gained general acceptance. Röntgenologically, it is a common finding to observe patients of the asthenic type with marked prolapsus of the transverse colon who do not, nevertheless, suffer from constipation. This state of affairs is illustrated in Figs. 4 and 5. Furthermore, constipated patients with such prolapse can be cured of their constipation without undergoing operation. A person of the asthenic habitus, with whom a general coloptosis is naturally associated with a neuropathic constitution, may at the same time suffer from functional constipation on account of his predisposition to anomalies of the neuromuscular

apparatus. Therefore, when one finds constipation associated with anatomical abnormalities, he should not neglect to inquire also into the functional state of the vegetative nervous system controlling the state of the bowel.

Weakness of the voluntary muscles that take an active part in the act of defecation is usually found in women after several childbirths; nevertheless, such weakness causes constipation in only a small percentage of women and it does not, as a rule, aggravate a condition of constipation already existing.

TYPES OF MECHANICAL CONSTIPATION

The principal types of mechanical constipation are: 1, the ascending type, and 2, the transverse type. There are, of course, many other forms of mechanical constipation, but the discussion of these types will be omitted, as it does not come within the purview of the present paper.

Ascending type.—This form may result from the presence of bands of adhesion affecting the ascending colon or from a large, relaxed and too freely movable cecum.

Transverse type.—In this form the transverse colon is prolapsed into the pelvis, forming a V shaped kink.

DIAGNOSIS

In the differential diagnosis of the constipations it is necessary to consider the following points:

1. Is the constipation mechanical or functional in origin?

2. If a mechanical cause is found, is it so serious as to demand surgical intervention; or will appropriate medical treatment bring about relief?

3. If the constipation is functional in origin, to which of the four types enumerated above does it belong?

Clinical aids to diagnosis.—If the complaint is centred on a lack of evacuation and there are no stomach complications, no colicky pains or other discomforts, the most probable cause is a hypokinetic type. If, on the other hand, the constipation is accompanied by colicky pains, meteorism and borborygmus, one's first thought should be of the dyskinetic type of constipation, so commonly associated with overactivity of the vagus. A rectal origin of constipation may be evidenced by a sense of fullness and pressure in the pelvis and by a frequent physiologic urge. The diagnosis should be established by digital examination. The ascending type of constipation is apt to be associated with fermentation or putrefaction.

X ray examination most important.—The most important part of the investigation of a case of constipation is the röntgenologic examination. This fact is illustrated by the x ray pictures that accompany this article.

TREATMENT

Intelligent treatment presupposes an exact knowledge of the type of constipation existing in a given case and of its causative factors with reference to the nervous system. No routine treatment of constipation is possible. It is obvious that the treatment that would be proper for a case of hypokinetic constipation would be entirely inappropriate in one of the dyskinetic type, of the ascending type, or of dyschesia. It is necessary to direct the treatment to the etiological factors.

Even in the hypokinetic type of constipation there is always also some degree of spasm. Therefore the treatment of any existing spasmophilia should be the first consideration. The drug that is most efficacious for the relief of spasm is atropine. Great care must be exercised in regulating the dose of this drug, because small quantities of atropine stimulate the Auerbach plexus, while large quantities inhibit it. Even after the condition is apparently cured, the atropine treatment must be continued for months afterward. In addition to atropine, other antispasmodics, such as bromide and luminal, may be used.

In the treatment of hypoperistalsis every effort should be made to discover the cause. Frequently various endocrine products, such as pituitary extract and Zülzer's neohormonal, may be employed. The vegetable or mineral purgatives are sometimes required. While these purgatives are being given, the patient must be kept under observation and the dose should be reduced gradually to nil.

Colonic irrigation should be employed only when there is local irritation in the sigmoid or rectum. For this purpose two hundred cubic centimetres of oil is best.

Some persons state that they are unable to have a movement until they smoke, drink a glass of water or go through some other preliminary performance. It must be understood that the defecation following such measures is attributable not to a direct action upon the Auerbach plexus but to the diffusion downward of an impulse that starts in the duodenum.

In certain psychoneurotic patients psychotherapy may be used in the treatment of constipation. Space does not permit of a consideration of this subject here.

DIET IN TREATMENT

Dietetic treatment is an important part of the measures to be employed in combating constipation. As a rule a diet of greater bulk with a larger amount of roughage is to be recommended. Stereotyped diet lists that pay no attention to the racial and individual prejudices of the patient are to be deprecated. The administration of bran is a useful adjuvant measure to the bulky diet.

In arranging a diet for the patient with the ascending type of constipation, it is advisable to start with a lighter diet and to gradually increase its bulk. First, farinaceous foods should be used, and then the vegetables should be increased gradually until the bulky diet commonly employed in the treatment of constipation is attained.

The treatment of dyschesia is important, but space does not permit of its consideration here.

SUMMARY

The nonsurgical constipations may be divided into two groups, namely, 1, those that are of mechanical origin, and 2, those that are of functional origin. But even in those cases in which röntgenological study shows a definite mechanical defect, the functional factor, i. e., a disturbance of the balance of the nervous control, is often the essential cause of the constipation.

A knowledge of the physiological action of the nerves that control the intestinal movements is essential to an understanding of the functional constipations. The most rational classification of these con-

stipations is that of Gustav Schwarz. It is based upon the present day conception of the nervous control of the movements of the colon. According to this classification the functional constipations are divided as follows: 1, the ascending type, which is commonly associated with pericecal adhesions, typhlitis, chronic appendicitis, and cecum mobile; 2, hypokinetic constipation, due to an underactivity of the motor vagal apparatus or an overactivity of the inhibitory sympathetic apparatus, or, just as important, an underexcitability of the Auerbach plexus itself; 3, dyskinetic constipation, due to an overactivity of the vagal fibres that pass directly from the intestinal serosa to the muscular layer, resulting in spasms; and 4, dyschesia or rectal constipation, due to a habitual suppression of the physiological urge.

The principal causes of the functional constipations are an insufficiency of roughage in the diet, diminution of the endocrine secretions that normally augment peristalsis, constitutional depression of the excitability of the plexus of Auerbach, overactivity of the sympathetic innervation of the gut, overactivity of the vagal innervation, and habitual neglect of the physiological call.

Whenever a patient gives constipation as his principal complaint, a detailed study must be made to determine the specific causative factors operative in the individual case. The most important part of this study is the röntgenological examination. A routine treatment for the functional constipations is illogical. Rational therapy is dependent upon the specific etiological factors in the given case.

A Plea for Early Operation in Diseases of the Gallbladder

HARRY PIKE, M.D.
New York

The medical literature seems to abound with ever increasing experience in gallbladder surgery, but there seems to be no unanimous opinion as to the operative indication for the diseases of the gallbladder and bile ducts.

Some surgeons recommend immediate operation, others late operation and others are opposed to any operative intervention. It seems rather strange that we cannot establish a definite operative indication, as in appendicitis, in order that the practitioner may make a definite decision for or against operation. The infection of the gallbladder may manifest itself in various ways. At operations all types of biliary conditions are seen, ranging from the simple inflammation of the gallbladder to the severest form of gangrene with perforation and peritonitis.

Frequently the inflammation will extend to the large organs, such as duodenum pylorus, head of pancreas and lymph spaces. As the inflammation of the gallbladder increases, the pressure in the bladder becomes more severe and the gallbladder distends until it bursts.

The great amount of pressure on its walls distends the bladder and this pressure is distributed equally on all its sides. The neck of the gallbladder distends until the impacted stone floats up and allows the infected bile to flow into the cystic and common ducts.

If the calculus does not float up into the bladder, some of the calculi remaining in the cystic and common ducts cause an infection of the duct and dilatation of the same with an infection of the surrounding tissues, which results in a dangerous condition for the patient. The pathological condition of the common duct will invariably follow if the diseased gallbladder is not removed. The common duct infection is preventable if the infected agent is removed early. That infection is a causative agent in gallbladder condition needs no proof. In case of the appendix, where inflammation spreads rapidly, the life of the individual is at stake, and it has been recognized after many years of argument urging surgeons not to wait, but to operate immediately as soon as the condition is diagnosed. In gallbladder conditions, because the apparent danger does not become so urgent, the tendency is to delay operation. The pathological complications which result from waiting will prove my contention that operation should be performed immediately.

I will cite a few cases which will prove that in diseases of the gallbladder operation should be as early as in acute appendicitis.

Case I.—Mrs. L. came to my office May 6, 1923, complaining of severe pain in the right upper abdomen. Her previous history showed attacks of indigestion, as she described it, for many years. This present illness started a few hours before coming to my office. She was seized with severe cramps. An examination disclosed severe rigidity over entire abdomen with shock. The patient was sent to the hospital. Operation showed a perforated bladder. The patient made good recovery.

Case II.—Mrs. M. Was called to see patient who was complaining of severe abdominal cramps. For the past ten years she had been complaining of attacks of pain in the region of the gallbladder. For the past few days she had severe attacks with vomiting. Ex-

amination showed rigidity of the upper abdomen and distended gallbladder. I advised operation but the patient refused. The next day the patient was sent to the hospital and I operated and found a perforated gallbladder. This shows that we should not procrastinate; even a few hours may cause severe abdominal crises.

Many medical men agree that some patients with gallbladder disease will recover without operation. Some patients with acute appendicitis will also recover without operation. This does not prevent the surgeon from operating in order to avoid severe abdominal conditions. There is I think sufficient reason for instituting the same treatment for gallbladder diseases. If we would treat gallbladder conditions the same as we treat appendicitis, we would reduce the mortality from gallbladder disease and probably obtain the same results as in appendicular conditions.

The dangers of operating in acute attacks of cholecystitis have been greatly exaggerated. Such danger is found to be no greater than operating in acute appendicitis. Delay in operating may cause damage to the surrounding tissues.

CONCLUSIONS

1. Cholecystitis is a surgical condition.
2. Common duct infection is a preventable condition in most cases.
3. Cholecystitis should be operated in acute stages.
4. Waiting for it to subside will cause a pathological condition in the surrounding structures and will endanger the patient's chance of recovery.
5. The gallbladder should be removed in all cases unless contraindicated.

Hypoleucocytosis Reversed by Nonspecific Protein Reaction

DAVID A. BRYCE, M.D.

Darien, Conn.

FOREWORD

I desire to report this single case of hypoleucocytosis (1) reversed by nonspecific protein reaction for the following reasons:

1. The completeness of the clinical and laboratory data involved point away from, rather than in the direction of, accident, coincident, or unknown factor, as here operative.
2. The special application, if any, of a well known procedure to young persons possessed of good vitality, seems well illustrated by the sequence of events in this case.
3. The use of this procedure in selected cases requires further study by other physicians: and it is hoped that they will give the matter critical study.

REPORT OF CASE

Case.—M. H. H., female, aged twenty-six, nullipara, white, native of the South, was admitted to Stamford Hospital on September 5, 1925. She had discharging ears and high fever. Six days previously the patient felt ill, but went swimming. The following day she felt worse. Subsequently pain developed in the left ear, then pain in the right ear. Dr. William B. White was called as consultant and a bilateral incision of tympanum done. This was followed by a fall in temperature, and later a rise. This was repeated two days later, and was also followed by a fall then a rise in temperature. Mastoid "tip tenderness" and redness developed. The renal and urinary systems were negative; the pulmonary system revealed slight cough for several weeks; the cardiac system gave no symptoms; no vomiting or gastrointestinal symptoms. There was slightly decreased mental acuity, but no other nervous symptoms. There had been suppression of the menses, for three months.

There had been no previous serious illness, and no operations. Her father died twenty-seven years ago of typhoid fever; mother and brothers were living and well. Hygiene and environment had been excellent throughout life; no alcohol or tobacco. Physical examination, on admission showed T:102, P:86 and R:22. The patient was a well developed adult white female. There were no signs of cranial nerve involvement; both ears were discharging; mastoids were tender; neck was negative. The chest showed slightly harsh breath sounds in both apices, no râles, no dulness. The heart showed no valvular lesion; bradycardia. The abdomen was normal. Reflexes were diminished. There was no Kernig's sign.

White cells
Blood pressure.

CONDUCT OF THE CASE

Röntgenological study showed bilateral mastoid involvement. Bilateral mastoidectomy was done on September 7, 1925, by Dr. William B. White, of Stamford. About twenty-four hours later the temperature rose suddenly to about 103°, and Dr. William Scrutan, otologist, of New York, was called in

consultation, who doubted sinus thrombosis. Radiographic study revealed a central pneumonia of the right lung. Later in the day the signs became evident as the whole lung was rapidly involved.

The accompanying chart shows with sufficient accuracy the salient features of the case from this point forward. When the leucocyte count reached 8000 in its steady fall, the condition of the patient was so extremely precarious that we decided, after consultation with Dr. Alfred G. Henderson, of Stamford, to try the nonspecific protein reaction. Accordingly following the suggestion of Graves (2), we gave one c.c. of sterile skimmed milk intramuscularly. Within twelve hours the effect (if it was an effect) was dramatic—improved blood pressure, leucocyte count, mentality, decreased delirium, improved respiration, pulse, etc. The subsequent course of the case was uneventful and a slow crisis occurred on the tenth day. The patient made an uncomplicated recovery and is well at her home in the South at the date of writing.

THEORETICAL CONSIDERATIONS

The basis of employment of the nonspecific protein reaction was the well recognized fact that clinically immunity production and high or rising leucocytosis go hand in hand. Obviously the increasing gravity of the disease in this case may have been due either to lowered pneumococcus opsonin, or diminished phagocytosis, or both. Without attempting any lengthy discussion of the many aspects of immunity involved, which I am not competent to discuss, I would nevertheless like to hazard a guess as to the cause and effect. It seems possible to me that for some unknown reason—possibly prior exposure to the specific organism (pneumococcus? the negative blood culture and absence of sputa make organism doubtful) in the middle ear—the defenses of the body became in a measure tolerant to this antigen, and as a consequence the bone marrow, spleen, liver, thymus, lymph glands, etc., failed further to respond by leucocytosis. The milk injection then not only increased the specific ("anti-milk") antibody function, but also all the antibodies in the blood. Phagocytosis and immunity were produced and the emergency was met.

CONCLUSION

Where hypoleucocytosis is met with during the course of lobar pneumonia in young persons whose resistance we should expect to be high—i. e., not in Type III, senile, postexanthematous, terminal, pneumonias—it is possible that this procedure is of value.

Experimental Investigations Into the Action of Salvarsan

JOSEF SCHUMACHER, M.D.

Berlin

(*Translated by Edward Ahlswede, M.D., Hamburg*)

(*Concluded from page* 509)

The solutions of the p-oxy-m-aminophenylarsinacid only reduce very slowly and feebly in low temperatures. One can observe that living yeast cells if treated with this substance do not stain brown with an ammoniated silver nitrate solution, hence they cannot have bound the arsin acid. On the other hand, the spirochetes treated *in vivo* with salvarsan still possess reducing properties. These reasons therefore exclude the alteration of salvarsan into p-oxy-m-aminophenylarsinacid, as the effective acting substance *in vivo.*

The p-oxy-m-aminophenylarsinoxide must also be eliminated as the possible primary alteration product of salvarsan *in vivo,* contrary to all assumptions up to date which I have endorsed for some time. The first argument against the primary development of p-oxy-m-aminophenylarsinoxide and its part as an effective ingredient is the fact that living cells which are treated with a one per cent. solution of this substance and are then rinsed and treated with an ammoniated silver nitrate solution, only stain feebly brown, thus having bound only comparatively little of the substance. This is not surprising as we know that only more pronounced lipoproteid soluble than water soluble agents, that is practically water insoluble agents, are selectively bound by spirochetes, whereas the oxide mentioned is readily soluble in water. Furthermore, as living yeast cells (these we emphasize here, react exactly in the same way as living spirochetes), if treated with a solution of one to one thousandth of p-oxy-aminophenylarsinoxide do not stain brown at all, and therefore develop no more traceable reducing capacities, while salvarsan, when administered *in vivo,* is much more diluted and the spirochetes nevertheless show a certain reducing power, it follows that the oxide mentioned cannot be looked upon as the primary alteration product of salvarsan in vivo. As the spirochetes still possess a comparatively high reducing power after their treatment with salvarsan *in vivo,* only a powerful reducing agent can be considered as the primary alteration product of salvarsan *in vivo.* Since we have eliminated the above arsin acid and the oxide, there remain for consideration only salvarsan as such and the salvarsan base as the effective substance which is "anchored" to the spirochetes.

Clinical observations also speak against the primary development of p-oxy-m-aminophenylarsinoxide as the effective alteration product of salvarsan and particularly the fact that the oxide mentioned is considerably more toxic than salvarsan. If all salvarsan, previously to its "anchoring" to the spirochetes, were altered into the arsinoxide mentioned, the proportion of the *dosis curativa* to the *dosis tox-*

ica would have to be the same. This is not the case. That is why, in my paper on stovarsol, I emphasized how improbable it was that the p-oxy-m-aminophenylarsinoxide could be the only effective alteration product of salvarsan. Salvarsan is less toxic than the oxide mentioned, because, when changed *in vivo,* as I shall point out later, the *water insoluble* salvarsan base is formed. The latter reacts with the vital constituents of the parasites and is selectively bound by these, whereas it cannot react with the vital constituents of the body cells, i. e., the nucleic acid containing nuclei. This can be demonstrated by subjecting living yeast cells, which abound in nucleoproteins, to intact salvarsan. On the other hand, the water soluble p-oxy-m-aminophenylarsinoxide is bound much more feebly by the spirochetes though still powerfully enough to be sufficiently effective. At the same time, being readily soluble in water (in addition to its basic nature) it reacts chemically with the acid cell nuclei, which fact readily explains its higher organotoxicity.

Hence, of the possible effective alteration products of salvarsan *in vivo,* only salvarsan itself or its base remain to be considered. Salvarsan as such (the dichlorhydrate) can be excluded immediately, as the experiments with living cells and intact salvarsan have shown that a binding of the latter by living cells is out of the question.

By exclusion, we therefore conclude that the salvarsan base alone can be considered the primary effective alteration product of salvarsan *in vivo,* as the powerful reducing capacity which the spirochetes still possess after salvarsan treatment *in vivo* points exclusively to a product with a powerful reducing capacity. Additional factors in favor of the alteration of salvarsan into its base are the fact that spirochetes can only bind selectively, practically water insoluble substances; furthermore, there is the comparatively low toxicity as compared with the p-oxy-m-aminophenylarsinoxide, reasons for which were given above.

How does the precipitation of the salvarsan base take place within the system following an intravenous injection of its dichlorhydrate (salvarsan)? One could say, briefly, that this precipitation is caused by the "atmospherilia" of the blood if one were to use this term. The oxygen and carbon dioxide content of the blood must have the same effect, as was shown above, with regard to the oxidation of salvarsan by air. The precipitation of the salvarsan base (which, by the way, must take place in a very effective colloidal form, under the given conditions) depends on the presence of certain ions. As experiments *in vitro* have shown that one can precipitate the salvarsan base out of its dichlorhydrate with calcium chloride, it would be particularly advantageous therapeutically, to keep the system saturated with calcium. Under these conditions the precipitation of the salvarsan base must take place more rapidly than in normal blood, the clinical effect must be quicker than under normal conditions and the toxicity must necessarily be reduced, as the total amount of salvarsan is directly changed into its base. This has in fact already been found empirically by clinicians. The reports of Wiesenack, Jacobsohn and Sklarz at the Clinic of Buschke deserve mention in this connection. Ziemann, also, in his discussion of my paper at the Berlin Microbiological Society (December 15, 1924) pointed out that large doses of neosalvarsan are tolerated if calcium is administered simultaneously. One should, therefore, inject salvarsan only when the body is saturated with calcium, or a calcium salt should be injected previously to the salvarsan, in order to reduce the toxicity of salvarsan on the body cell.

Within the limited space available we can only briefly outline the clinical questions involved and must reserve further details for future publications.

The reason why tabes and progressive paralysis benefit so little from salvarsan medication is explained in the following manner: We know that normally, practically no salvarsan reaches the brain, as it is prevented from doing so by the normal protective apparatus of the system. This protection is provided by the *vascular endothelia* and the histocytes as well as by those organs which abound in lipoproteids, such as the liver and spleen. The latter, owing to the lipoproteid content of their protoplasm, bind a large part of the salvarsan similarly to the parasites, for which reason salvarsan soon disappears from the circulation and has no time to penetrate the vascular endothelia. However, if this protective apparatus is diseased or if we inject larger doses of salvarsan than the elements of the developing base mentioned are capable of binding, some salvarsan will reach the brain with the well known deleterious results. The lipoproteids of the brain are naturally just as capable of binding the salvarsan base *selectively* as the parasites, provided pathologic conditions give them a chance. This is proved by the mere fact that salvarsan is more than one hundred times as toxic by intraspinal injection, if it is allowed to react with the lipoproteids of the cord and brain. These organs are known to consist chiefly of lipoids and lipoproteids. It is therefore utterly impossible to influence the spirochetes located in the brain or cord for purely chemical reasons which must be accepted as given facts, as every molecule of the salvarsan base is immediately bound by the lipoproteids of these organs before it has any chance of reaching the colonies of spirochetes usually located at a certain depth. Hence the pronounced toxicity of intraspinal injections and the small therapeutic benefit derived therefrom. The spirochetes are protected in the brain and the cord against the attack of lipoproteid solvents similarly to the manner in which the lipoid containing nucleus of the spores of microorganisms is protected by the lipoproteid containing spore membrane.

In the first instance the disinfectants are bound by the lipoids and lipoproteids of the organs in question and can therefore no longer reach the parasites; in the second case the lipoproteid of the spore membrane forms a barrier with the desinfectant, beyond which it is difficult for the latter to penetrate. Chemically this barrier would consist of a salt of the particular lipoid acid and the corresponding base of the disinfectant employed. There can be little doubt, of course, that spirochetes *in* the spinal fluid and those located in the superficial layers of the cord and brain are devitalized in these cases. However, those parasites which are located within the organs do not succumb to the spirillicide action. Therapeutically one must, therefore, attempt to influence these indirectly via the body cells by a catalytic hastening of the oxi-

dation processes *in vivo*, which coincides with a rapid increase of the antibody production. Insoluble mercuric salts are generally used for this purpose on account of their prolonged and lasting action in the above sense. In my opinion one should, however, not attempt to achieve this sterilization by inoculating another disease (i. e., malaria) into an already syphilitic patient. The aim should rather be along the lines of modern chemotherapy, to determine what chemical products are formed by the system when a syphilitic infection takes place and why an increase of their production seems to occur in the presence of malaria plasmodia?

This question is important for future microchemical investigations.

We already have certain clues as to how the system responds in these cases. However malaria treatment cannot yet be advised for more than the treatment of progressive paralysis before more light has been brought into these relations. The method of choice must still be to influence the parasites indirectly, as energetically as possible, by combining metal salt treatment (as the most effective indirect antisyphilitic) with lipoid therapy. Strictly speaking, empirical investigators have already chosen this method of treatment by infecting their patients with malaria plasmodia and recurrens spirochetes, both of which contain a high percentage of lipoproteid. From the aforesaid one can also conclude that Ehrlich, by creating his old salvarsan, had already found the best antisyphilitic. Neosalvarsan, being more readily soluble in water, is considerably less effective therapeutically. Our experiments on living yeast cells show that roughly ten times the dose of neosalvarsan (as compared with old salvarsan) is required in order to guarantee the same intense therapeutic effect. This has in fact been repeatedly emphasized. Only recently Arning emphasized the superiority of old salvarsan over all other salvarsan compounds. We now know the reasons for this optimum clinical reaction. As already stated, the reasons are the extreme lipoid solubility of the salvarsan base compared with the much poorer solubility of the neosalvarsan base in these media. All the other "improvements" of salvarsan cannot be acknowledged as such, at least from our own investigations. I have not had time to test the preparation of Albert. One must add here that Ehrlich and the manufacturers of neosalvarsan had already found that the latter is less effective therapeutically than old salvarsan, though they did not know the reason therefor.

One important clinical observation may be mentioned here. Experience has shown conclusively that an abortive cure is possible only up to a certain time limit. Beyond this limit the cure practically always fails, as Kolle has shown by animal experiments. This time limit, in my opinion, coincides with the moment at which the spirochetes invade the brain, where they cannot be destroyed no matter how large a dose of salvarsan is administered. This is the reason why Buschke and Kroo apparently succeeded in sterilizing their recurrens mice with salvarsan. However, when they inoculated some of the brain substance of these "sterilized" mice into other animals, all of the latter were infected, the reason being that the recurrens parasites, which chiefly consist of a lipoid albumin compound, *cannot* be devitalized in the brain (which also abounds in lipoproteids) either by salvarsan, as such, or by its alteration product the salvarsan base, any more than can the Spirochæta pallida.

If these experiments had been made with a knowledge of the chemical structure of the spirochetes and the alteration of salvarsan in the system, the results could have been predicted. This, in fact, distinguishes exact microchemical research from the customary empirical method of investigation, as the latter cannot *predict* anything and usually has to sacrifice host of animals before any question can be decided.

We conclude from the foregoing that intensive treatment with medium large doses of old salvarsan is the method of choice, on the basis of microchemical investigation. Powerful blows and not pin pricks are advisable, as I already pointed out years ago. To secure a lasting effect it is also advisable to go back to intramuscular injections. Painful infiltrations can be avoided as I expect to communicate later.

In cases of fresh syphilitic infection, our investigations show that a course of salvarsan treatment should precede mercuric treatment, in order to devitalize, with the salvarsan base, all the parasites possible within reach directly with one blow. If this has been achieved, or if, in an advanced stage of the infection this treatment does not promise the destruction of all parasites, one must aim at an indirect destruction *via the body cell*, by catalytically increasing the production of antibodies, as explained above. Mercury must still be considered the agent of choice for these purposes even if a certain benefit must be conceded to bismuth in this respect.

The reason why salvarsan is more easily tolerated after a preceding mercurial injection is the fact that the latter is followed by a certain leucocytosis as a result of the defensive reaction of the body against mercury ions, with the result that only a *small part* of the salvarsan in a subsequent salvarsan injection can exert its action, as the lipoproteids of the leucocytes which then constitute quite a considerable factor, bind a large amount of the developing salvarsan base chemically, thereby inhibiting to an extent its action on cells and parasites.

CONCLUSION AND SUMMARY

What must be the chemical structure of an effective chemotherapeutic antisyphilitic agent? We know that we can now influence syphilis therapeutically in two ways: a, by attempting to damage the parasites *indirectly* via the body cells, or b, by attacking them *directly* with a spirillicide agent, that is with a genuine chemotherapeutic agent in the strict sense of the word. In the first case we choose metallic salts which are now known to act catalytically by hastening the oxidation processes *in vivo*, thereby hastening the cell activity and subsequently the production of antibodies. In the second case we try to destroy the parasites, possibly with one blow, though this has not always been found possible in practice. Salvarsan is chiefly used for the latter purpose. If we consider its mode of action as explained above, we are now in a position to determine *definitely* how an antisyphilic chemotherapeutic agent should be built up. Such an agent must, as far as we can judge at the present time, meet at least the following demands:

1. The agent must be able to react chemically with the living spirochete; if not, its alteration product *in vivo*, at least, must be capable of doing so.

2. The agent must possess oxygen abstracting properties, that is it must be capable of exerting an inhibitive influence on oxidative syntheses, so that the natural differences between the chemical structure of the body and spirochete cells are taken advantage of therapeutically. The agent must consequently exert the very opposite effect of metal salts, which act indirectly.

3. Inasmuch as its action depends on an abstraction of oxygen, the agent should preferably possess pronounced reducing capacities which would increase the above mentioned action. As experience has shown that the abstraction of oxygen, which is effected by the arseno group during its oxidation, is in itself sufficient to effect a devitalization of the spirochetes, the powerful reducing properties of an arsenical are not a *conditio sine qua non.*

4. The agent should possibly be a substance of a pronounced basic nature and should therefore not contain more or less powerful acid groups (no carboxyl, sulphurated or arsanilated groups) as experience has proved that these preparations develop a weaker affinity for the spirochetes than the former. This is the reason why Ehrlich found arsenicals with trivalences to be more effective than those with pentavalences.

5. The agent or its alteration product *in vivo* must be more markedly lipoid soluble than water soluble in order to be bound selectively by the spirochetes. This reduced water solubility diminishes the organotoxicity of the preparation. In addition, the selective binding of the compound by the spirochetes, directs the toxic action of the preparation almost exclusively against the parasites. This alone can furnish the desirable margin between the curative dose and the toxic dose, thus guaranteeing a favorable therapeutic index.

6. The agent, as such, or rather its alteration products *in vivo,* must possess a strong chemical affinity for the parasites and *none* for the body cells. Every agent which acts *directly* on the pallida, that is every chemotherapeutic agent in the strict sense, even if future findings should base its action on a different principle than that of oxygen abstraction, must meet demand (5), as an optimum therapeutic index is not imaginable otherwise, for the five reasons given. If we consider the properties of salvarsan one can see that Ehrlich has built it up most ingeniously. It meets all the demands of a chemotherapeutic agent against lues, with the exception of demand 6.

No preparation can meet this demand as these conditions represent given factors which are inherent in the chemical structure of the body and parasite cell with which we simply have to put up. Nor should we yield to illusions and expect preparations other than salvarsan to be capable of definitely destroying the parasites *with one blow* in the advanced stage of the infection. The above, therefore, represent the minimum requisites for a modern chemotherapeutic antisyphilitic agent.

One can also judge from the aforesaid why I was able to predict one and a half years ago that bismuth could not be considered a chemotherapeutic agent in the stricter sense. None of the bismuth compounds which have been employed so far, with the exception perhaps of the very latest triphenylbismuth of Giemsa, meets the above demands. Nor has it yet been decided whether the action of the Giemsa preparation is due to bismuth or possibly to the *total molecule.* This might be possible as bismuth is very firmly bound chemically in Giemsa's compound and can therefore be only feebly active itself.

I might add here that my criticism of earlier days has in the meantime been confirmed by the animal experiments of Kolle who discovered everything we had predicted of bismuth, with our histochemical knowledge (11), as one can gather from one of Kolle's recent publications (12). If one considers furthermore the expenses involved in the experimental test of one single bismuth compound only, of which I happen to know, and then considers that 2,400 bismuth compounds were tested in France, as Kolle mentioned in his Frankfurt paper, one can obtain an idea of the enormous sums frequently wasted on empirical experiments in similar cases.

From the foregoing it follows that all arsenicals with pentavalences, provided they meet the demands mentioned above, must be serviceable antisyphilitic agents. We may also expect a certain spirillicide action from antimony compounds with low valences for the same reasons which apply to arsenic. Practical experiments have already proved this. Other substances with a similar chemotherapeutic action on spirochetes, to mention a few examples only, may be expected among the quinines and the dyes, provided they have been previously altered in such a way as to meet the demands chemically. Logically animal experiments alone can determine their definite value.

One must not forget to emphasize the fact that hitherto we have only found *two* differences between the spirochete and body cell which can be exploited therapeutically: the (varying) content of oxygen and the absence of nucleic acid in the pallida, to which we now add the third difference, the lipoid content.

If we succeed in penetrating deeper into these microchemical relations and should discover more differences in the chemical structures, it is not improbable that other substances of therapeutic value might be found which owe their properties to *other differences* in the chemical structures of the two cell species and would in accordance have to meet other demands than those enumerated above.

These ideas may also serve as a guide in the chemotherapeutic attack against other infectious diseases.

The microchemical investigations on the differences between the chemical structure of the body cell, on the one hand, and the parasite to be combated one the other, should if possible be completed *before* any animal experiments are made.

Microchemistry and chemotherapy should cooperate. *Corpora non agunt, nisi fixata.* The investigations discussed above again prove the truth of this old slogan of Ehrlich.

Our present knowledge of the fact that we are by no means limited to water soluble substances chemotherapeutically, while pronounced lipoid soluble substances are selectively bound by the spirochetes and many other microorganisms, will probably be of no little importance in the future development of chemotherapy.

Instruments, Apparatus, and Clinical Notes

The Treatment of Dorsal Spinal Caries

J. B. BARNETT, M.D.

London, England

The difficulty of treating tuberculous caries of the dorsal vertebræ is only too well known. Not only is collapse early and acute, abscesses common and large, but even a small, final angulation tends to throw the whole vertebral column out of truth, and result in serious secondary changes in the thorax, and lumbar spine. It is in the dorsal region, too, that most difficulty is met with in preserving immobility during treatment, and in establishing the compensatory curves necessitated by collapse and ankylosis of the vertebræ.

Apart from operation, treatment by relative immobilization has been practised by many forms of apparatus—some, now happily obsolete—varying from the comparative fixity of a plaster jacket, to the freedom and ease of suspension from a Fisher, or other, frame. It is difficult to obtain local heliotherapy in most types of apparatus which result in flattening of the thorax and wasting of muscles, and the most ardent advocate of external fixation must admit that no apparatus will maintain even relative mobility without injurious pressure. It is notoriously difficult to keep a child quiet once the pain has gone, and the usual strait waistcoat apparatus interferes with sun treatment. Certainly, the body may be exposed in sections, as in the plaster bed and front case method, but this involves movement of the whole body.

So, this rough scheme of treatment of a typical case is offered in a tentative spirit, in the hope that it may interest those who treat these cases, and provoke a helpful criticism.

When admitted, in the acute stage, the child is treated on his face, propped up by pillows under the shoulders (Fig. 1). Reins are worn, consisting of two soft rings fastened over the back, and held in front by a strap which passes around the bed. This latter is of the simplest possible description, cheap, mobile, and with a laced canvas top. They are made in the hospital workshops. The child is maintained in a position of hyperextension, with the hips extended, and the knees flexed over a pillow, which also protects the toes from pressure. The ankles are tied loosely to the foot of the bed, and the rings to the top. Nursing is simple, a pillow being slid out from under the pelvis when necessary. Bed clothes are easily applied, but normally the patient remains stripped as soon as full pigmentation is obtained. The method we use is to expose the whole body to the sun for two minutes the first time, doubling the dose day by day, and checking the dose by the skin reaction. In dull weather, exposure to skyshine is allowed for half an hour for the first dose.

Treated in this manner, the child's pain and tenderness are at once relieved, the angular curve flattens to a marked degree, and muscle spasm becomes less. Treated on the back, as by the more common methods, the thoracic viscera press on the diseased area, and local heliotherapy is impossible. Treated on the face, the vertebral column is relieved from weight, the spinal muscles improve in tone instead of becoming atrophied, and so far as we can tell, the local focus of disease improves much more rapidly.

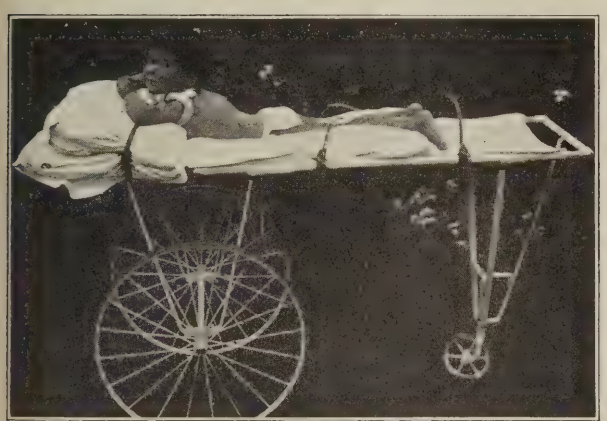

Fig. 1.—Showing child lying on his face, propped up with pillows under the shoulders.

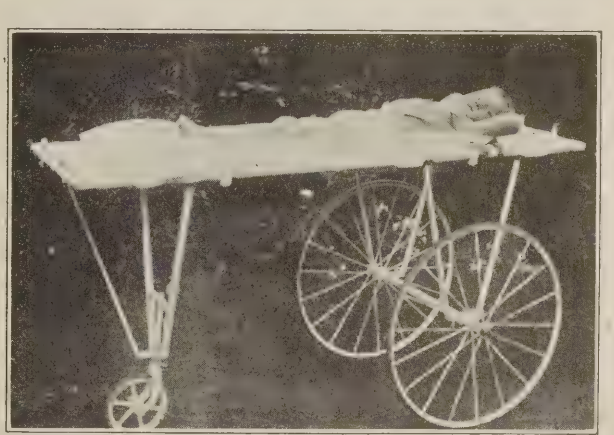

Fig. 2.—Showing child some weeks later, turned on his back. The condition is good and pain absent.

After some weeks, when the general condition is good, pain completely absent, and muscle spasm only local, the child is turned on his back (Fig. 2). A short plaster bed is made, in moderate hyperextension, and fitted snugly down to the canvas of the frame by a few small sandbags. The same position of the spine and lower limbs is maintained, and reins are worn. It is at this time that relative immobility of the spine is so important, and so hard to obtain. Malleable iron prongs are fitted to the frame so that one passes over each shoulder, one over each side of the pelvis, and one over each thigh. These prongs are so tempered as to be easily bent by the surgeon's

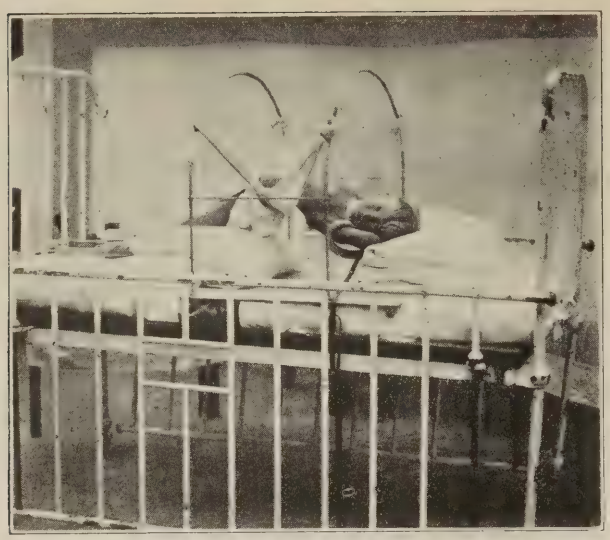

Fig. 3.—Showing the child slung from cradle by bands crossing diagonally, a pad fitted to the kyphus.

hands, but so tough as to resist the strength of a child. They are pressed down until they nearly touch the skin, and are clamped to the frame. The consequence is, that if the patient moves, the prongs dig into his skin, and he learns within the first day that in immobility alone lies comfort. By invoking the patient's cooperation in this manner relative immobility is assured, and yet the apparatus does not interfere with sun treatment. At this time he is allowed to move his legs to a limited extent.

When all pain, tenderness and muscle spasm have been absent for three months, and the x ray appearances of the spine are encouraging, the child is once more turned on to his face, in the hyperextended position. He is fastened merely by reins at the shoulders, and can move about on his bed to his heart's content. It is now that heliotherapy is of the greatest importance, to aid in building up the spinal muscles, and indeed, in most cases, a very satisfactory muscular development may be obtained. He is kept for a further three months or so in this position, and meanwhile a spinal support is made for him, fitted in suspension. When at last he commences to get up, massage to the legs is commenced, and wedges fitted to the inner side of the boots, to correct the almost inevitable relaxation knock knee.

In those cases where an ugly and damaging kyphosis has persisted, compensation is obtained in this wise. The child is slung from a heavy cradle, by bands crossing diagonally under a pad fitted to the kyphus. These are arranged in such a manner that there is a pull downwards from each end of the curve, as well as a push upward at the curve itself (Fig. 3). In other words, the patient's own weight is used to obtain a mechanical effect somewhat similar to the Marconi apparatus, but in a more simple and inexpensive manner. A few weeks on this cradle produces considerable compensatory curves. Naturally, discrimination must be exercised, and only cases absolutely quiescent, and having a collapse of not more than two vertebræ, are considered suitable.

Fig. 4.—Same patient as in Figs. 1, 2 and 3, showing results of treatment.

Abscesses are treated by antagonizing the force of gravity, and are not aspirated when acute unless involving the skin. For instance, if a psoas abscess presents, the foot of the bed is raised on blocks, and usually, these abscesses disappear, to be no more seen except in radiographs. It would seem that the sudden relief of pressure obtained by aspirating an acute abscess only leads to further exudation into its cavity, and so, working on this hypothesis, abscesses are only aspirated when the wall is thickening, and consolidation commencing. Of course, if one approaches the skin, it is a different matter, owing to the risk of secondary infection.

By this scheme of treatment we hope to obtain a cure with a straight back (and strong muscles to keep it straight), and only a small kyphus with one projecting vertebra. Since the natural cure appears to be by collapse of one or more bodies, prevention of any collapse at all would appear to be a dangerous matter—as indeed, some have found. The results obtained so far by these methods are at least encouraging (Fig. 4).

Observations on the Osgood-Sclatter Disease.—Robert Ollerenshaw (*British Medical Journal*, November 21, 1925) thinks that this lesion is a fracture and should be treated as such by complete immobilization for six weeks. He finds that the best immobilization is achieved by a well fitting plaster cast, fitted close to the limb and moulded closely round the knee. It reaches from the groin to the ankle and, while it is worn, walking is permitted. After the removal of the cast massage is instituted and a knee cage, with a stop allowing only forty-five degrees flexion, is worn for a further six weeks. The cases which the author has seen where symptoms have persisted for months or years, and which have been called "apophysitis," "periostitis" either traumatic or mildly infective, or the like, have in every instance been the cases which have not been treated by immobilization, but where continued strain has been allowed to take place. Most of these cases which one sees later in the course of the disease settle down well and consolidate if completely immobilized in the same manner as is advised for the recent cases, but a few cases of long standing where a tender nonunion exists are improved by operative fixation of the fragment to the diaphysis. In more than half of the author's series of cases girls were affected, though it is generally stated that the condition is more frequent in boys.

Alteration of Character, Disposition, and Behavior, as a Sequela of Encephalitis Lethargica

ALFRED GORDON, M.D.

Philadelphia

Objective neurological manifestations of an organic character as a consequence of an attack of encephalitis lethargica have been exhaustively studied and elaborately reported. Mental phenomena have also been observed but in a smaller number of cases. In the latter the psychic alterations are usually without definite intellectual disturbances. The impression, however, may be gained, especially in the Parkinsonian types, that there is a postencephalitic depressive psychosis, but in reality the mental condition is an akinetic expression in the psychic activities analogous to the akinesia in the motor sphere. In all such cases the mental processes run parallel to the motor phenomena, including the speech which is characteristically slow. In some cases the depression may become very deep and the patients show no tendency to analyze, criticize or investigate events and occurrences in their environment. Such cases may then simulate a demented state; in reality there is no genuine dementia but only a generalized akinesia involving the entire psychomotor sphere. Contrary to depressive states encephalitis lethargica may be followed by states of euphoria but this is a rare occurrence; very few such cases are on record.

Besides the purely psychotic phenomena analogous to those observed in the classical types of psychoses there is another set of manifestations which are more frequently observed, especially in young persons and children, which constitute a more difficult problem for solution and therapeutic management, and which comparatively speaking have been neglected. I have reference to alterations of disposition, character, emotivity, and behavior. The following group of cases came under my observation within the last two years:

Case I.—L. S. T., a boy aged thirteen years, had encephalitis lethargica about four years ago. The objective symptoms were typical and very pronounced. Bulbar disturbances were in evidence. Difficulty in swallowing and hoarseness were very disturbing to the patient. He had been confined to bed eight months because of an unusual state of asthenia. The convalescence was slow. It was only eighteen months after the onset of the disease that he commenced to show rapid improvement. He was able to be about, grew strong, and had a voracious appetite.

At that time he commenced to show peculiarities in behavior. He returned to school but was unmanageable, while before his illness he was quite obedient and attentive. He was very irritating to the teacher and pupils. He became mischievous, would annoy the boys of the class by pulling their clothes, cutting their hair with scissors, and spotting them with ink. When reprimanded by the teachers he would become violently angry, use profane language, spit at everybody around him, use physical force, throw books and any object which was handy, break windows. He was not amenable to reason and no one, including his parents, could pacify him before the spell of anger was over. Then he appeared sad, depressed and full of regret. He could not be kept in school, the teachers being unable to control the situation.

At home he mistreated his two small sisters, particularly the baby sister, whom he would frequently spill out of the crib, finding a special delight in doing it. However, he promptly expressed regrets for having done it. Frequently he would strike his mother when she contradicted him. When in his presence she complained to me of his behavior, he screamed at the top of his voice, pounded on the floor, and called her unprintable names. On the other hand, when she would happen to be indisposed, even very slightly, he would give her all his attention, sit by her bed for hours, be alert for anything she would ask of him, and frequently shed tears when she mentioned the word pain.

On several occasions he promised to behave better and be obedient if he would be permitted to return to school, but no sooner would he be admitted than the teacher would be compelled to send him home because of the disturbances he created in school. He would frequently lie and invent occurrences which never took place. He stole money and not rarely trifling objects such as toothpicks, nails, etc. When reprimanded, he always expressed deep regret with constant promises not to repeat the acts, but all in vain; he invariably returned to his misbehavior.

Intellectually he was alert; his memory was excel-

lent; in spite of his being absent from school for many months, he was able to recall all he ever learned. He was very quick in mathematical problems, and frequently exhibited good judgment in matters of a serious character. The management of the case was exceedingly difficult, as on one hand the parents were not intelligent enough to understand the situation fully, the father punishing him with violence. On the other hand the school authorities insisted on considering him mentally deficient and placing him in a special school for feebleminded children. The patient rebelled against this. When put among the defective boys he violently protested, giving everybody more trouble than in the regular school. With tears in his eyes he implored me to intercede for him, stating that he should be given another chance, but again all in vain, as he promptly returned to his mischievous behavior.

Such was the patient's condition for twenty months without the least change in his disposition and behavior. Somatically he presented, as sequelæ of encephalitis, internal strabismus and frequent attacks of dyspnea. Soon, however, he commenced to show signs of improvement. Gradually the outbursts of anger became rarer and rarer; the remarks or advice of his parents were more frequently listened to by him. Sleep was more profound than heretofore, the restlessness became less. However, it was noticed that frequently and without provocation tears appeared in his eyes. He became very emotional. If any one of his brothers or sisters happened to be injured, he would run promptly to their rescue, and exhibit a caressing and highly solicitous attitude towards them. He began to show a great interest in study. Serious subjects attracted him now much more than at any time prior to his illness. He would go to the library where he would spend hours in reading books on history. He refused to play with other boys, but would go out with some of the boys for walks. He commenced to speak of future plans, had a desire to resume school studies and to graduate for the purpose of obtaining a college education. He became very attentive to his personal appearance. He treated everyone with proper consideration.

Physically he was in excellent condition. The attacks of dyspnea, however, continued. He asked for relief as they were very distressing. He finally returned to school and began to make rapid progress and made up unusually well for the lost time.

At the present writing the boy is well and normal with the exception of the dyspnea which, however, occurs only on rare occasions. The family history of the boy was free from any mental or nervous disorders or any constitutional disease.

CASE II.—L. S., a girl of fifteen, was in good health up to 1920; she was of good disposition and possessed normal intellectual faculties. At that time she had an attack of encephalitis lethargica, with all the typical symptoms—somnolence, diplopia, ptosis, and fever. The course of the disease was very long and only at the end of the sixth month all the physical symptoms disappeared, when another group of phenomena made their appearance. First of all, she complained of vertigo and attacks of excessive perspiration and there were also evident mild choreiform movements on the right side. In the next place, she began to be very talkative and erotic; she would smile at every man whom she happened to meet and she was frequently found at the window of her room without clothes. She became careless and very euphoric. She was obstinate, mischievous, always in trouble with her people, misbehaving on the street, making remarks about everyone who happened to walk in front of her. She quarrelled with her brothers and parents and was very impertinent. At times she was found in a dreamy state, would not answer when spoken to. She became careless about her personal appearance and unclean. She lost interest in her relatives and became indifferent to them. When reproached for it she would only smile, promise to do better but her sentiments remained the same. She manifested a tendency to misrepresent, to lie about things that actually never occurred. On one occasion she said she found a pocketbook full of money but when asked to show it she answered that she distributed the money among poor people. She also told her mother that a wealthy man proposed to marry her, provided she left her parents at once.

Her general appearance was good, the intellect was lucid, at no time were there hallucinations or any other sign of delusive reasoning. Her family history showed abnormal features. The grandfather was alcoholic, one aunt was in an insane asylum, one first cousin was a mental defective. The patient had in childhood convulsive seizures from the age of two to six and had a meningeal attack of unknown character at ten for which she was confined to bed for eleven months and during which she was at different periods delirious.

CASE III.—M. D., a boy of seventeen, was in excellent physical and mental condition up to the age of fifteen. He was then stricken with an attack of encephalitis lethargica for which he was bedridden during a period of three months. He made a complete physical recovery, but his behavior and character underwent a radical change. As fond as he was of school work prior to his illness, he now decided for himself not to return to school, lost all desire for intellectual work and found a commercial position. He soon left for another position. He did this several times. He was unable to remain in one place for longer than one or two weeks. This restlessness and instability were evident in his general conduct and relationship to others, including his own family. He became lazy, nonchalant, disinterested in everything and everybody. He had violent outbreaks of anger, would attack and assault anyone who happened to contradict him. Lying was an outstanding feature; intentionally and without any provocation he would speak ill about his friends and his own parents; he accused the latter of depriving him of the most necessary things, such as food and clothing. He masturbated violently and became indecent in his conversations with females or males. His criticism reached such a degree that once he was arrested for making a profane proposal to a married woman on the street. He suffered from insomnia and became exhausted upon the least exertion. He had frontal headache. A test for intellectual ability gave excellent results. His memory was good. He was able to discuss intelligently almost any topic of the day, but in doing so there was a strong tendency to bring forward his own personality as the last word of logic and reason. Vanity was predominant: he spoke of many plans and

projects that he expected to bring to realization. A somatic examination brought out markedly increased kneejerks with a bilateral toe phenomenon.

He is still under observation and there is not the slightest tendency to a favorable change in the disposition, behavior or in the emotional sphere. The family history revealed two cases of idiopathic epilepsy and one case of dementia precox, all in cousins. The mother is hypochondriacal. The patient had several attacks of acute chorea in his early childhood.

Case IV.—G. R., a boy of ten, had an attack of encephalitis lethargica at the age of seven which lasted four months. As a physical sequela there were myoclonic movements of the muscles of the neck, which are still present in a mild degree. The recovery from the encephalitis was followed by a total transformation of the child's disposition and behavior. While formerly he was considered as possessing an intelligence above the average, now he had great difficulty in remembering even the most recent events. To comprehend the simplest problems of arithmetic he was compelled to spend considerable time in figuring. When spoken to he frowns and tries visibly to understand the words, but the expression of his face shows that the patient is under great mental strain and effort during the entire conversation.

Prior to his illness he was very active and was considered a leader by his schoolmates; now he is totally lacking in initiative; whatever he does, is done by him automatically. He becomes easily aroused and irritated while formerly he was mild and gentle. At times he is impulsive and throws objects at anyone who happens to contradict him. He is very vindictive. Another peculiarity observed in the boy is that he seeks the company of much younger children, while formerly he enjoyed being among older boys.

His condition has remained unaltered for the last sixteen months. His general health is good. The family history shows a neuropathic taint in many members. The father is alcoholic and was before he married. One uncle was confined to an institution for the insane for two and a half years.

Case V.—G. S., a girl of sixteen years, while in perfect health suddenly manifested encephalitis lethargica. Recovery followed in three months. A slight paresis of the left internal rectus muscle remained. Prior to this illness she was of excellent intelligence, had a splendid record in school, was of a loving disposition and particularly fond of her mother. Following the encephalitis a radical change took place in her. While intelligence remained intact, she was unusually irritable especially when her mother would address her. She was restless and impatient, could not sleep, had outbursts of excitement in which she became very aggressive and at times brutal in language and action. She became very domineering towards her sisters and friends; her wishes had to be carried out promptly as otherwise offending remarks and at times actual attempts to attack on her part would follow. Her affection for her relatives had considerably decreased. Formerly, when her baby sister would awaken at night and cry, the patient was the only one in the house who would give her attention for hours. At present she is totally indifferent to anything that may happen, she pays no attention to crying or to pain affecting anyone in the household.

Prior to her illness she was sexually indifferent from an objective viewpoint. Now she exhibits considerable eroticism in the presence of men. She masturbates frequently. Somatically there is nothing to mention except increased tendon reflexes and a slight paresis of the left external rectus muscle. The intellect is intact and above the average. The family history is unfavorable to the patient; the father is exceedingly emotional, the mother is neuropathic, having frequent periods of obsessions, also of depression. One brother also had several attacks of mental depression.[1]

A review of the histories of the cases just reported brings out the following essential characteristics of postencephalitic sequelæ in the domain of the emotional sphere. Aggressiveness, hostility, impulsiveness, outbursts of excitement or anger easily provoked or occurring without the least external stimulation, restlessness, discontentment and dissatisfaction; a tendency to misrepresent or frankly to lie without any specific motive; a tendency to misappropriate or to steal; excessive eroticism accompanied or not by selfabuse.

What characterizes particularly this group of symptoms which could be conveniently called "psychomotor instability," is that they did not occur periodically or at more or less regular intervals similar to those observed in cases of maniacal or hypomaniacal states, but they presented continuous states without intervallary periods analogous to the purely motor manifestations of lethargic encephalitis in which the symptoms exist for a long time without modifications. The group of symptoms outlined above, therefore, cannot be considered parallel to the clinical pictures observed in the classical psychoses. While individually they may be encountered in several types of psychoses, nevertheless collectively they cannot be identified with the latter. They constitute a clinical entity apart because they involve almost exclusively the domain of emotional forces, but not of the intellectual forces. The latter were invariably intact in everyone of my cases as well as in similar cases reported in the literature. Indeed, a careful mental examination failed to reveal any disturbance whatsoever in the domain of association of ideas or in judgment. Consequently in all such cases we witness a distinct *dissociation* between the psychomotor instability which was so strikingly present in each of the cases described above and the integrity of the intellect strictly speaking. Everyone of the the individual characteristics enumerated above is not the expression of a profound mental disorder encountered in typical psychoses. For example, stealing and lying or committing fraud are but the external manifestations of a morbid impulse of which the patients are fully conscious and which they regret after the commission of the impulsive act.

Affectivity may at first glance appear to be seriously involved, as we have seen in the majority of the cases, so that to give one the impression of a true psychosis in its early development, such as dementia precox, but in reality this is not the case. Disturbance of the affect may also be encountered in mental defectives or as an isolated symptom in psychoneurotics, but in all such cases the patients are not fully or

[1]This study included two more cases, which have been omitted for lack of space. They will be included in the author's reprints.

not at all aware of the true significance of the disorders; they are not in the least moved or otherwise even touched when their damaging conduct causes considerable annoyance or actual physical inconvenience to those who are interested in them.

In the postencephalitic cases, on the contrary, the patients are very sensitive to the consequences of their deviations from the proper conduct and in some cases we witness genuine regret with a state of anxiety and a painful criticism of their behavior which is after all not voluntary, is not thought out, or deliberate. Besides, these morbid acts, which are the consequence of change of character, are only transient and periodical, they are amenable to amelioration and even to recovery, but they are not the result of a fundamental mental disorder. On the other hand, one must not forget that in spite of this knowledge and criticism of wrong conduct and behavior, in spite of the painful and anxiety state that the latter causes to the patient himself, there is nevertheless existent a morbid emotional state, and the effect is here involved only in its reactions and in the power of execution, but not in its central power.

A similar diagnostic interpretation and meaning we find in another manifestation, namely, in the excessive eroticism which was present in each of the cases of the series. Here as well as in other individual features of the altered character and in behavior following encephalitis, we are dealing merely with an expression of disturbed inhibition and automatism as the result. The intentional forces and the tendencies are intact. From this very same viewpoint the defective or psychotic individuals present a different picture. In them the various tendencies naturally deprived of moral restraint show no indication of the existence of sentimental or altruistic considerations. The execution of these tendencies may be identical with those of the encephalitic cases, but what is at fault is the superior psychic power which is at the basis of the activity in psychotics and defectives. Pursuing further our comparative study, we are led to see in all these behavior characteristics the same lack of regulating or inhibitory influence as in the motor sphere of postencephalitic parkinsonian syndrome in which hypertonicity is such a striking symptom.

If we consider the anatomical substratum of encephalitis lethargica, in which the most important and most constant lesions are found in the mesencephalon, and if we are also mindful of the function of the latter as recent studies lead us to believe, namely, that the purely mechanical action of coordination and reaction is controlled by this portion of the brain, all the psychomotor characteristics under discussion are easily conceived and explained. We must therefore admit that modifications of behavior observed in cases of encephalitis lethargica do not belong to the category of purely psychotic phenomena and that the individuals thus affected are not to be considered as being affected with mental disorders in accordance with the well established classical psychoses. We are dealing here exclusively with emotional phenomena which are only superficially involved.

There is another phase of the subject which deserves special mention, namely, the prognostic outlook of the personality disorder. A study of the seven cases recorded here shows that the individuals whose personal and family histories present evidences of character and behavior disorder, or psychotic phenomena of any nature, had unusually long duration of their postencephalitic disturbances, as at the time of writing this article the psychomotor instability was still present in all its intensity in spite of the fact that three years had already elapsed since its onset. On the other hand, the patients whose antecedents were totally free from disturbances in the psychic sphere, made a complete recovery.

It seems, therefore, that the postencephalitic cases follow the same laws as hereditary influences which we observe in mental abnormalities originating from any source. Emotional disorders, profound or superficial, short or long in duration, associated or not with purely psychic phenomena although they present the same clinical picture in hereditary and nonhereditary cases, nevertheless show a difference in both categories from the viewpoint of prognosis. Their persistence or disappearance depends upon the degree of constitutional fragility.

Another conclusion that can be drawn from the present study is: A postencephalitic mental symptom-group may develop in individuals heretofore perfectly normal and totally free from any predisposing factor. An infectious condition, such as lethargic encephalitis, may disturb the psychomotor tone and the inhibitory system, irrespective of individual tendencies and habits which are being controlled by this system. It stands to reason that should special morbid characteristics be present before the invasion of the encephalitis, they will become more accentuated whether they belong to the intellectual or to the emotional spheres. The presence of a hereditary predisposition is not a *sine qua non* condition for development of a postencephalitic mental symptom-group. Being of a purely emotional character and not of purely psychotic nature the postencephalitic manifestations discussed in the present contribution may tentatively find their physiological explanation in the alteration of the basal ganglia which are invariably involved in encephalitis lethargica and which, we have some reasons to believe, are ordinarily concerned in emotional phenomena. The inevitable inference seems to be that midbrain disorders are associated with behavior disturbances, that the latter are consequently organic in nature, and are a counterpart of the motor disturbances following encephalitis.

Analogous personality changes have been observed in association with some affection of the floor of the third ventricle. M. Meyer (1) calls special attention to MacNeil Donald's case of a man, aged twenty-five, who, following an encephalitis, presented marked character disturbances. He had been formerly upright and in every way reputable; he began to fabricate, became untruthful and morally delinquent, but at no time did he show impairment of intelligence. Examination revealed a typical picture of dystrophia adiposogenitalis.

The accumulated observations point more and more to an organic rather than to a psychogenic conception of postencephalitic behavior phenomena.

A Psychoanalytic Introduction to a Study of the Conduct Disorders of Lethargic Encephalitis*

With Outline of Plan for Psychosocial Reconstruction

L. PIERCE CLARK, M.D.

New York

INTRODUCTION

A survey of the extensive bibliography on the subject of epidemic encephalitis shows that the etiology and treatment of this disease occupy a conspicuous place in the medical literature of the day. Welfare agencies are equally concerned with the social implication of this socalled sleeping sickness as the sequelæ of this disorder often result in conduct difficulties that make it impossible for these subjects to be cared for either at home, by social agencies, reformatories, state hospitals or institutions for the feebleminded. All these systems of care have been tried. It is found that society is dealing with a crippled person who, though neither criminal, insane, nor mentally subnormal is yet unable to adjust to any recognized social code. He is irresponsible and often comes in conflict with the law, but the basis of his disorder is medical, not legal. What is to be done with him? What is the emotional level of his deterioration? Where can an understanding treatment be undertaken, a suitable environment be arranged, and what is the probable prognosis of this disorder? These are some of the perplexing questions that form the basis for the data and suggestions to be presented. Here it is interesting to note that in working out the material submitted, further evidence is found that definite changes in disposition and behavior result when the disease attacks a child's developing brain, whereas an attack in an adult tends perhaps to a more physical expression of the inflammatory process.

The medical aspects of lethargic encephalitis have been developed far in advance of an understanding program for its treatment. I propose therefore: to give a brief outline of the problem; report upon trial and error efforts undertaken by social agencies to fit these dynamically unstable individuals into the rigid and limited provisions of a modern community; discuss the intensive training of a typical case in a young girl whose symptoms were radically improved after a period of ten months psychoanalytic reeducation in an observation home; give a partially analyzed case, with suggestions for future care that might be undertaken with a more profound analytic interpretation of the patients' emotional needs; and finally, propose a plan for organizing an observation home for the intensive study and training of a group of cases.

In 1922 an intensive study of lethargic encephalitis was made in various States. From New York, Boston, New Haven and Chicago it was learned that the epidemic was greater than the community imagined, and the sequelæ developed at a later date were bringing these individuals to the fore. As many as forty to fifty cases were brought to one clinic alone, with absolutely no solution worked out for them, and there were no hospitals or institutions prepared to care for this type. Such patients could be sent to psychopathic hospitals but nothing would be gained thereby. Diagnosis had already been made and what the patients needed was a comprehensive understanding of their particular problem and how best it could be met, and not merely custodial supervision. Throughout New York, Connecticut and Massachusetts a large number of cases were without any type of care.

The social problem met with everywhere may be summarized in the following typical case:

CASE.—An eight year old girl, quiet, well behaved, was making unusually good progress in school until the onset of this disease. One month after her discharge from the hospital she was readmitted with a history of a complete character change. She ran away from home and stayed away for days at a time. The school was unable to keep her on account of her noisy and quarrelsome habits. Neighbors complained about her stealing and destroying and her abuse of other children. Her second period in the hospital was brief, as she was constantly in a highly excitable state. She was sent to a hospital for the insane but was discharged in less than a month as unsuited for the type of care provided. At home she was found to be entirely uncontrollable. Arrangements were then made for a period of treatment in an institution for the feebleminded. The child, with an intelligence quotient of 108, remained here for six months. She was paroled home but her stay was brief, due to a return of the old antisocial characteristics; she was again returned to the state institution, from which the following information was recently received: "This girl is not a mental defective, but she continues to exhibit such bad personality traits and outbursts of violent temper that it seems likely she will have to remain permanently under custodial care."

This case, typical of many others, well illustrates the amount of time and labor spent by welfare agencies in producing unsatisfactory and unilluminating results. In forty cases studied in Connecticut, five patients remain acute social problems, five have died, seven have not been heard from, nine have been reported to have recovered under ordinary care, and the remaining twenty-three have been reabsorbed in the community in spite of varying degrees of physical and mental impairment. After analyzing these results, the conclusion was reached that the problem could be met adequately only through organizing a temporary study home, which would develop care and treatment suitable for children suffering from the sequelæ of this disease. A detailed plan for such a home was submitted at my suggestion to the National Committee of Mental Hygiene.

In a review of the progress made in psychopathology within the past decade we find two distinct lines

*Read before New York Neurological Society, February 2, 1926.

of research. The older one has aided to perfect our comprehension of the transference neuroses, to make more plain their genetic origin and to give us a more secure and lasting therapy. The other line of research is a more venturesome effort to resolve the ego neuroses into their component origins, and even to approximate some means of direct handling of organic disease supposedly based on functional or constitutional defect. In this latter field there are two methods of approach. The first is to recognize that there is an array of functional disturbances present, as in disorders of motility, circulatory disturbances, and the like; and the aim, therefore, has been to devote time primarily to reducing these syndromes to their supposed psychogenic origin for amelioration or cure. For the most part it is an attempt to comprehend neurotic disorders upon a neurologic or biologic basis, which, while not incompatible with well known psychoanalytic views, is closely interwoven with intellectual symbols that make the plan of therapy largely expositive and reeducational (such as my older work on tics). In spite of this rather formal and mechanical method of approach excellent progress has been made by the patients, and it is urged by many that this method of treatment is the "more reasonable" one, and will encounter less immediate resistance although the release of symptoms is less permanent and perhaps the method is only a little removed from the current systems of psychotherapy exclusive and often opposed to real psychoanalysis.

The second method quite as surely recognizes the physical disorders as entities but that very little can be done directly with the symptoms as such. To look upon such sick persons as possessing far graver disorders of character and personality of which the immediate and pressing syndromes are but a part of their real disorder, is the unique position of the latter method. To sidetrack for the time being the whole gamut of symptoms and require the patient to give heed to the long circuitous route by which his predicament has come about, calls for extreme fortitude on the part of both the patient and the physician. It may well be that for some time to come the "more reasonable" psychoanalytic reeducation by the didactic method directed to current symptoms which are immediately pressing for abatement, and then gradually lead the patient back to the graver faults of character from which the symptoms originated, will still be our chief interest and study. To accept functional and constitutional disorders as organic neuroses which are slightly removed or more deeply set into the structural pattern than the now more definitely outlined narcistic neuroses, requires only a little more scientific courage than was shown by Freud and his coworkers a few decades ago when they rescued the transference neuroses from the baleful category of organic disease. Perhaps we shall make more rapid progress in understanding these socalled functional or true neuroses as well as many constitutional diseases (even such diseases as tuberculosis and arteriosclerosis) by a more careful analysis of the egoneuroses and their narcistic fixations. The latter can be, perhaps, best understood only by a more painstaking analysis of the derivations of character in the infantile period, which may be undertaken by a variety of methods as Ferenczi, Rank, Abraham and Jones have shown. Without power of direct memory recall of this infantile period, it is astonishing how Freud (who calls it the pregenital period) has so accurately outlined the difficulties which we may expect to encounter in this twilight zone of conscious formulations. From the reaction formations induced by the educational repression of the instincts we may infer the influence which many of these unbridled instincts exercise in all adult living, and any direct testimony of their objective or subjective dominance will be doubly welcome. The final admixture of instincts and their repression which form character in its broadest sense, will be the next attack for understanding behavior as well as all life reactions independent of immediate social adaptations. With a desire to advance our general progress in understanding the egoneuroses and finally socalled organic disease, this study has been primarily undertaken.

From my data to be presented here and elsewhere, one is at a loss to see how an extension of neural and functional explanation can be of much aid in interpreting the occurrence of conduct disorders as a sequela to epidemic encephalitis. In point of fact there is no evidence that the residual lesion left in the wake of this disorder has any direct bearing upon the conduct syndrome as such, any more than the occurrence of this neurosis in general is caused by an organic lesion. How, then, are we to consider this apparent causal relationship between the organic lesion and its neurotic sequela? I think we must assume quite another relationship than a direct one. We must look upon the lesion here as one that singularly wounds the psyche and personality of its victim, not in a somatic and physiological sense, but in a psychological one. The breakdown of a neural interpretation of a sequential mental syndrome is not unique. It extends equally all over the field of mental disorders following organic cerebral lesions. Very recently Hollós and Ferenczi (1) have shown that even in such a paradigm of a supposedly organic disease as paresis, the display of mental symptoms is greatly to be explained upon the lesion acting as a sort of releasor of unconscious and repressed instinctive forces. On the face of it, aside from the very intensity of endurance of the conduct disorders sequent to encephalitis, the neurotic state does not essentially differ from the same clinical expression where no such lesions occur. That being the case, the direct causal relationship breaks down even more signally than has been shown in the paretic study just cited for the euphoria of paresis and its dire termination may be a unique clinical experience. In other words, there is nothing so like the clinical picture of paresis outside its classic instance in the metaluetic lesion of this well known disorder. All kinds of cerebral lesions in infancy and childhood are singularly apt to leave mental stigma in various forms of mental arrest or enfeeblement which are particularly stubborn to remove. Practically up to the present time, the degree of mental impairment such sustain at the time of their cerebral lesion remains hopeless throughout life. The latter are as enduring as the lesion which seemingly is responsible for them. Singularly enough, however, there is no sustained ratio between the kind and degree of cerebral lesion and the psychic symptoms supposed to

cause them. Many efforts have been made to correlate the lesion directly with the mental syndrome, but these studies have borne little practical result. It has been stated (Southard) that dementia is as marked in cases showing no cerebral lesion as those presenting it. It is also well known that both profound idiocy and epilepsy may also occur without any at present discernible lesion. Hence one might logically infer that the degree and extent of cerebral lesions are independent of any known causal relationship. If this be true, why should we attempt any longer to maintain direct or recondite explanations of the connection between neural and psychic injuries? Yet in spite of this improbability renewed efforts are constantly being made to bridge the gap between neural and psychic patterns upon an organic or physiological interpretation. All of us surmise that there must be some relationship, but the majority have given up any direct causal one. Even Sherrington is frank in saying that at present he sees no possible bridge by which we may connect body and mind. In view of such a despairing state of affairs, any theory which promises a reasonable explanation may be put forward as a tentative line for study.

For a long time we have known that these children suffering from mental and epileptic defects are about as amenable to disciplinary and educational training as their noncerebral lesioned fellows. In point of fact it is often assumed that greater amelioration might be expected in cerebrally injured cases because the inherent germ plasm has not suffered the same degradation as the supposedly hereditary ones. However this may be, both classes are treated when feasible along psychogenic lines, quite independent of any particular cerebral injury which they may have suffered. The lines of treatment which have been found to be of most value are less of the intellectual sort *per se,* but are rather industrial and occupational so that the natural instincts of emotional interest can be best utilized. In other words, the main reliance is placed upon the natural trend of the instincts and the hopeful encouragement to build up the character and personality. Due allowance is placed upon the aid of ambition and esthetic and social stimuli. In brief, the line of treatment holds egoistic appeal in its best and largest sense. How much do we actually know of the wounded psyche in the fearfully handicapped cerebral cases? Practically nothing. Vague guesses by psychometric tests may be made quantatively but how about the qualitative understanding of these children? Is the latter the same as the hereditarily handicapped ones? Probably not. Certainly but few attempts have been made at really understanding the unconscious in these cases; particularly none has been made for the post-encephalitic conduct disorders. The state has been excellently described by social workers, neurologists and psychiatrists, but no deep analysis has been forthcoming. Have they intensive psychic conflicts comparable to the neuroses in which sadistic and homicidal acts occur? We can only surmise that if they do exist they are of a more severe and enduring sort, comparable to those of the savage or the very young and undisciplined child. Moreover, they invariably occur in childhood and adolescents wherein the social or psychic pattern is but recently acquired and is probably most easily upset. The main difficulty in any thorough analysis, up to the present at least, is that this conduct disorder is an ego neurosis, and incapable of ordinary transference or the transference is too slender and unstable to make it enduring through the period necessary to make a complete analysis. Now that we may enter the unconscious of the ego neuroses through the phantasy method I believe that the psychoanalytic study of these cases will be less hopeless and probably no more difficult to study than the stubborn and set epileptic youth. In psychoanalytic terms, these conduct disorders are none other than acute narcistic neuroses organically conditioned. It would seem that the psyche through the disorder of the respiratory and circulatory apparatus is being continually disturbed. We now know from similar neurotic disorders that there is a somatic as well as psychic component of narcism. Various types of hypochondria are instances of involvement of one or both of these conceptual systems. The anal and oral erotic behaviors of these conducts disorders are glaringly manifest in postencephalitic adolescents.

Naturally no one would assume that we underestimate the primordial rôle or significance of the purely somatic symptoms of lethargic encephalitis. The psychic symptoms to which we shall chiefly address our remarks are defect symptoms and irritations directly resulting from the somatic process. The natural symptoms correspond to the inadequate dominance of the psyche over the narcistic libido aggregated and held in, as it were, by the cerebral lesion.

In an attempted hypothetical explanation we may assume that the conduct disorders in postencephalitic children are a special variety of cerebral pathoneurosis in which the ego organ, the brain, has been injured. The excess of the libido complement (narcisism) which has been mobilized to drive the ego to accomplish or fulfill its functions, breaks down the more tranquil adaptations evidenced in the person before his encephalitis occurred. The youthful patient is therefore thrown back upon a utilization of earlier behaviors and stages of development which were once more or less successfully passed. We know that libido is stored up in the total economy of the individual ego. This is the sum total of the libido in the individual organs and their mutual cooperation of organic as well as functional living. This libido gradually divides or directs itself into two main polarities of living, one toward the various erogenous zones and ultimately placed to the service of the sexual aim, and the other toward the preservation of the individual as a personal ego. The interchangeability and cooperation of these two polarities of the libido perhaps enter into every human relationship, but for the time being we shall give our main concern to the ego portion of this total libido formation, as it is the part singularly deeply wounded in the encephalitic individual. This ego libido is not a separate entity for the functioning of these organs, the brain and its adnexa, but enters into the power of regenerating or healing these organs once damaged. A confirmation of this assumption was found in certain observations on traumatic neuroses during the war. The fact was established that a shock accompanied by severe wounding left behind either no

traumatic affect or one much less important than a shock without bodily injury. This apparent paradox becomes intelligible only if one assumes that the narcisistic libido mobilized by the trauma is used (libido which psychoanalysis places as the primary cause of the traumatic neurosis). In the case of an injury received simultaneously, partly in pathoneurotic libido, it is held prisoner in the wounded organ, with the result that it can no longer fluctuate freely, nor operate as a cause of neurosis.

As we may now point out, Freud has shown that there is no bodily organ which does not possess or manifest some essential influence over the total libido. The brain is essentially the organ of the ego function libido, as the peripheral erogenous zones transmit their self gratification ultimately to the genital zone. Thus we have these two great divisions of the total libido acting often in the most elaborated intricacy in the maintenance of social relations.

The lethargic encephalitic process not only produces symptoms of defect but upsets the tranquil order of the narcisistic libido which is manifested in conduct disorders with the ego thrown out of peaceful balance with the outer world. The neurasthenic symptoms are often masked by the lethargic states which master the patient's life. The traumatic neuroses are analogous to this condition. Moreover, as we may rightly infer, as the lethargic state disappears the conduct disorders put in an appearance, usually in proportion as the totality of libido egoistically and objectively is withdrawn from the previous living activities. For instance, we shall see in the brief case notes to be cited, as the lethargy passes away the neurasthenic symptoms are quickly transformed into hypochondriacal symptoms physically manifested, most usually in the field of ambition or ego outlets. When a patient makes use of a narcisistic transference, one notes the marked alleviation of many of the mental and conduct disorders. As Freud states, these actual hypochondriacal neurotic symptoms are the result of the painful storing up of narcisistic libido in the ego functions. If this storing up of narcisistic libido surpasses its utilization in social living, it must be mastered psychically (endured or repressed by effort of will), and if this is insufficient, then the patient exhibits conduct disorders at times of stress or diminished periods of rest. It may be that the continued states of periodic lethargy or sleep are to be explained upon this secondary effort at compensation, acting as a sort of miniature psychic reverberation of the shock of the original lesion, or a reenactment of its affect comparable to the repetition compulsion physically shown in the post traumatic neuroses in tremors and fright as well as the type of dreams. Many of these syndromes in postlethargic encephalitics may be similarly explained on psychogenic reenactment principles, and not solely to a continued ascending and descending generative process sequent to the initial lesion. At least the degenerative lesion often continues to injure the partially corrected functioning of the narcisistically wounded ego organ, and the conduct disorder may carry a just but none the less disquieting compensation for the kind and degree of libidinal outlet normally denied. Thus the conduct symptoms are a pathoneurotic hypochondria of a positive sort not covered by lethargy and may be looked upon as psychic overcompensations for mental defects encountered as well as a pathoneurosis in which there is an intensification of the narcisistic libido provoked by organic disease.

(*To be continued*)

Reaction Types in Cancer

JOHN HOLLAND CASSITY, M.D.
Washington, D. C.

The more recent physicomathematical contributions of the relativists (1), with their time-space revelations, seem to adequately substantiate the earlier hypotheses of the philosophers Vaihinger (2) and F. A. Lange (3) in regard to the nature of matter. The first mentioned philosopher held the view that "matter forms an entirely empty and meaningless subject for the forces and is but an inaccurate aftereffect of a view which has grown accustomed to the idea of extended and separate bodies and which also assumes substance as bearers of elementary forces." This roughly coincides with the present opinion of Russell (4) who avers that "matter is a logical fiction, invented because it gives a convenient way of stating causal laws..... Matter is, after all, inferred from its appearances which are used to verify physical laws." With this in mind, it seems that scientific investigators should be somewhat chary of talking with too great assurance of mental and physical causations in disease processes. In considering cancer here, it is with assiduity that we have avoided the misleading terms mental and physical.

Kretschmer (5) has demonstrated the synchronous occurrence of constant morphological features with certain psychic disease entities, schizophrenia and affect disturbances for example. To illustrate, he classifies the human organisms under consideration into pyknic, asthenic and athletic morphological types, and he discovers that the latter two are more prone to develop schizophrenic reactions and that the former is usually of the extroverted type so susceptible to affect disorder. Bleuler (6) alludes to syntonic and schizoid types of organisms by way of transcending the dualistic implications of mental and physical aspects. Meyer (7) and his coworkers long ago acquired the habit of considering behavior of individuals in terms of reaction types and personality makeups, in contrast to the older and more rigid classificatory systems. Brill (8) sums up the situation simply in regard to the normal individual by stating that "even in normal persons one often sees the syntonic (pyknic type of Kretschmer, extrovert, manic) changing at puberty to a schizoid, or vice-versa. But, on the whole, one can follow a definite

reaction of a preponderating type throughout life. No one has more earnestly enunciated the importance of studying the organism as a whole than W. A. White (9), who reminds us in no unmistakable terms that "a host of visceral conditions are already recognized as having some sort of neuropathic determiners (spastic conditions in the gastrointestinal tracts such as spastic colon, pylorospasm, etc. which lead to organic changes such as gastric or duodenal ulcer); it is entirely within the scope of reason to look for psychogenic factors in such diseases as diabetes mellitus, particularly of the adrenalogenic type, etc." Working also in this direction have been Kempf (10), with his mechanistic investigations, and Lewis (11), stressing the constitutional factors in psychic disorders by noting definite somatic changes taking place in cases of schizophrenia in contradistinction to unlike somatic changes occurring in affect disturbances and paranoia.

In cancer, similarly, the cases studied tended to group themselves rather consistently into similar morphological and personality reaction types.

The cases studied were grouped as follows: ten normal cases, fourteen autopsied psychopathological cases, five living psychopathological cases.

In the normal cases, morphological grouping, according to Kretschmer, was effected, in addition to rather detailed personality studies after the manner of Amsden and Koch. Due emphasis was laid on the organism types of Bleuler (syntonic, schizoid, etc.).

In the living psychopathological group, the case histories were briefly abstracted from the hospital records, and a short description of the psychic problem was included in addition to a statement of the hospital diagnosis. The autopsied psychopathological cases were considered only from the viewpoint of the hospital diagnosis and the autopsy findings.

The manner in which these organismic reactions were studied is illustrated by the two type cases appended below, the first being a nonpsychopathological case, the second a psychopathological one.

Following this, is presented a table, which it is hoped will be selfexplanatory.

A NORMAL CASE

CASE I.—White male, aged fifty-six, seen in private practice.

Kretschmer features.—This man was a robust, plethoric individual of medium height. Extensive rolls of fat were superimposed on the flabby musculature and loose connective tissue work of the body. He had an unusually large head, with high forehead and hair extending well back from the brow. His eyes were large and deeply set and his gaze was rather direct and severe and commanded respect. His mandible was heavy and suggested tenacity. The huge cranial case, the Irish nose and the short, thick neck gave the man a distinct bull dog effect.

Longitudinal section.—Even as a child, this patient was said to be selfwilled and stubborn by those who knew him best. He was the type who, after being soundly flogged for an offense, would impishly, and even impudently, repeat the tabooed cavorting. On the other hand, however, he manifested at times marked signs of tender heartedness. When any of his family were in trouble, he, too restrained by pride to be observed giving in to his feelings, would come in with his face tear streaked and proceed brazenly to avoid any suspicion that he had been at all moved. In play at school, he was looked up to as an undisputable captain in games of the rougher sort. When volunteers were called for pranks of more hazardous variety, he invariably would choose the part that required grit. His teachers regarded him as a brilliant student but an uncertain one as far as deportment was concerned. He married at twenty-five, shortly after organizing a business in New Orleans, which incidentally has been a thriving one. He managed to support a family of six from the proceeds of this business. The atmosphere about his home, according to his wife, was always cheerful and lively though one significant glance from "the old man" was sufficient to bring about a quiescence of activities. In business and social activities, this man was extremely active, in fact, an officer in two leading business clubs. Further, he and his wife entertained frequently, surrounding themselves more particularly with warm personal friends rather than more impersonal social acquaintances.

Cross section.—If a stranger were asked to label the distinct characteristics of this man's behavior upon first seeing him, he would unhesitatingly refer to his brusqueness. When I first came in contact with this man, I remarked upon this trait to his wife and she said: "You just don't understand him—that apparent gruffness he has developed to serve as a mask for his tender heartedness." He discussed his life very freely and extracted not a little secret amusement out of attempting to frustrate the "kiddish looking" doctor. Once that superficial crust had been penetrated, the examiner discovered a most charming and engaging personality, and before his several weeks of conversations had terminated, we had formed a very warm friendship. His approach was always prefaced by that mock severity which I later found to be in reality his playfulness.

Cancer symptomatology.—He had an extensive carcinoma of the rectum which had manifested itself in years of digestive disorder and which culminated in intestinal obstruction, finally leading to his demise.

A PSYCHOTIC CASE

CASE II.—*Kretschmer features.*—This was a large woman, tending toward obesity. The size of the bulky breasts and of the pendulous abdomen gives the thoracic and abdominal regions a circumference out of proportion to that of the thighs. The cranial case was very large for a female and the forehead was high and spacious. The nose was broad and stubbed and the lips full and firm. The heavy mandible and prominent mental processes tended to complete a rough outline of a hexagon. A line drawn from the centre of the forehead to the point of the chin would be very close to straight. The facial expression was frank and forceful; her gaze was alert and bespoke interest in her surroundings.

Longitudinal section.—Patient's father was eccentric and mother was a suicide when patient was seven years old. She was then sent to a young women's home. Her school life was uneventful and she seemed to make quite a satisfactory adjustment. She married at twenty-two a rather successful newspaper man in Cincinnati. The patient, being rather sociably inclined, developed rather grandiose ambitions

to become prominent in society. Her husband, becoming unable to cope financially with her extreme demands, was finally forced to yield to divorce. He was very reasonable, however, and paid generous alimony; in fact, enough to send his wife and daughter to Paris, where the latter could learn French. After remaining in Europe for six years, the patient returned to America, and her first mental symptoms became manifest. She developed ideas of her husband's unfaithfulness and alleged that he was spying upon her, and in addition that various men whistled at her with the intention of making a conquest.

Cross section.—Upon admission to the hospital she harped dramatically upon being grossly insulted by various men. She was quite communicative, however, and seemed to obtain pleasure in her misery, that is, by affecting dramatic byplays to attract the examiner's sympathy. She projected her difficulties on various men with whom she would come in contact about the grounds and was always eager to pour out her tale of woe. The mental reaction was a rather typical paranoid type, and only adds to our conviction that the paranoid mechanism is more often linked with extroversion than with the shutin personality.

Autopsy.—She succumbed to carcinomatosis of the liver. The autopsy revealed, in addition, a moderate arteriosclerosis and myocarditis and general glandular hypertrophy.

REACTION TYPES

	Bleuler-Brill		Kretschmer			
	Schizoid "Shut-in" Introvert	*Syntonic Open Extrovert*	*Asthenic*	*Athletic*	*Pyknic*	*Mixed*
Ten living normal cases	2	8	1	2	7	0
Six living psychopathological cases	1	5	0	1	5	0
Totals	3	13	1	3	12	0

DIAGNOSTIC CHART

(St. Elizabeth's Hospital Diagnosis)

	Hebephrenic	*Catatonic*	*Manic*	*Paranoid*	*Epileptic*
Six living psychopathological cases	1	0	2	3	0
Twenty-one autopsied psychopathological cases	1	0	5	13	2
Totals	2	0	7	16	2

No cases of endocrine dysfunction were discovered among the living cases.

Three paranoids and one manic among the autopsied cases were found to have general circulatory and glandular hypertrophy.

It is evident hence that even by excluding borderline types, ninety per cent. of the cases studied fall unequivocally into the category of extroversion and syntony. Shut-in types are conspicuous by their scarcity, there being only two present in the whole series.

Among psychopathological cases, paranoid mechanisms and affect reactions constitute the rule. Reversely, no catatonic types are present and only one case was diagnosed hebephrenia. Further, no case could be placed in the asthenic group of Kretschmer's reaction types.

It should be noted that in the presentation of the reactions in these cases no mention was made of the rôle played by psychic conflicts in tissue proliferation. In my own experience I have not been able to connect definitely the appearance of cancer with the predisposing psychic conflict. In one case, however, the cervical carcinoma occurred in a rather suggestive time relationship to the thwarting of a desire for a large family, the childbearing being suddenly and rudely halted by a husband's unfaithfulness. The patient's apparent reaction was a development of a lasting antipathy toward men plus the excitation of a tissue protest—Nature's seeming protest against interference with her biological processes. Similarly, in another there developed a carcinoma shortly subsequent to the death of a brother. He incidentally succumbed to an attack of melancholia following the demise of this same relation. Though these factors are possibly inconsequential, I merely mention them for what they are worth in view of the fact that Goddeck (12) reported a tumor of the breast occurring concomitantly with an unmistakable conflict in one of his cases. The tumor proved to be noncancerous because of its disappearance but was diagnosed clinically by a cancer specialist as malignant. The swelling was attributed to the memories of a copy of Titian's "Flora" which had hung over her parents' bed, but was more deeply related to what occurred at the time of her mother's second confinement, when the patient was obliged to assume the nursing responsibilities of a younger sister for whom she developed strongly libidinous ties. The synchronous disappearance of the tumor, with euphoriation and exposure of the undeniable homosexual complex, led the author to assume a psychic foundation for the somatic transmutation. Any assumption of this sort would be warranted, however, only by the complete exclusion of all other possible foundations for these tissue changes by means of exhaustive methods. Deutsch (13) is convinced that "the psychic conflict may express itself in pathological changes in organs over which the patient has no conscious control." He mentions further that tumor of the stomach has been produced by nervous stimuli and "can continue to be formed provided the stimuli worked long enough and be of sufficient intensity."

In spite of the fact that these studies fail to conclusively establish a psychic foundation for somatic change, they at least validate the contention that the solution of the cancer problem will lack completeness so long as the psychic component be regarded as a negligible one. Though the discoveries of Gye and Barnard (14) are possibly epochmaking in their significance, the fact that the predominantly syntonic types of human beings appear to possess a greater susceptibility for malignancy than the less retaliative schizoid ones cannot be disregarded.

The Infectious Nature of Facial Paralysis

With Report of Cases Due to Focal Infection

CARROL B. WELTON, M.D.
Peoria, Ill.

All of the older and most of the recent literature and textbooks on the subject, give exposure to cold as the etiological basis of Bell's palsy, in about seventy per cent. of cases. Eighty per cent. of all cases of paralysis of the facial nerve are of the peripheral type—complete motor paralysis. Since first described by Charles Bell in 1823, it, more often than any other peripheral nerve, is affected alone (Steinart) and the explanation of its cause has remained an enigma in the practise of medicine. Bell's description of facial palsy chiefly concerned itself with the flaccid condition of the facial muscles, the rolling up and out of the eye on the affected side on attempts to close the eyelid and did not note the disturbances of taste, smell, and hearing. The majority of patients probably have some of the latter symptoms if inquiry is made. The "exposure of the face to cold or prolonged drafts of air, of sudden chilling of the body while in a state of perspiration" is supposed by recent authors to happen in patients of the type known as the rheumatic group, and it is supposed to be, therefore, in these patients that the great majority of cases of paralysis of the facial nerve appears. Neumann and Charcot attribute the nerve palsy to inherited nervous disease susceptibility, and not to the effects of chill of head or body. From all sorts of fantastic explanations the majority of writers on the subject have attributed it to socalled exposure.

Some of the theories advanced in elucidation of the phenomena have been unique, Reik believing that in the peripheral form in most cases the middle ear is involved. At first supposed to follow exposure, about which the patients are closely questioned, this history was obtainable in about seventy per cent. of the cases. Then the neuroanatomical theory (Phillips) was advanced of the bony canal being congenitally narrow where the nerve makes its exit from the skull, an elaborate series of measurements taken and tending to substantiate this theory, a considerable variation was found to exist in the specimens examined (Leiner). The diameter of the stylomastoid foramina even differed in the same skull, the right being found in a large percentage narrower than the left, and in different specimens ranged from a hair's breadth diameter to one quarter inch in size. It can be stated now that when one considers the size of such a canal, after the lumen is still further narrowed by the lining periosteal membrane, the slightest effusion at this place would easily make the necessary pressure to stop function in the nerve. Palsy of the right side does occur clinically twice as frequently as on the left side.

Later the socalled rheumatic group was projected into the exposure theory and careful investigation found that a majority of cases of Bell's palsy occurred among the socalled rheumatic type, although this is denied by some and this dissenting view is supported by the fact that treatment along rheumatic lines gives no relief in the disease. After analysis of all the theories on which the etiology of facial paralysis is based, the fact remains that while exposure and narrow canals may be predisposing causes of facial palsy, neither these nor any other proposals so far advance a satisfactory explanation, unless as a basis, infection about the head is taken into account. With the presence of infection in close proximity to the nerve, it is not difficult to understand how these foci become active in the production of nerve involvement when the general bodily resistance of the individual is temporarily lowered by chill of air, moisture or what not.

Pershing states that "rheumatic and idiopathic cases should always be regarded as possibly infectious and a thorough search be made for a primary focus," and he advocates "prompt removal of any source of infection as the paramount indication." Dana in his textbook on neurology believes that Bell's palsy "is a microbic infection similar to that of 'colds' and influenza and that it is not a rheumatic disease but an infection and should be so classified." Jackson thinks a few cases seem of toxic origin. In April, 1925, Dabney specifically calls attention to the infectious nature of facial paralysis and reports four cases in which prompt amelioration and cure resulted where infective foci in the head were eradicated. He believes every case of Bell's palsy of toxic origin and says, "if careful search be instituted, the causal factor can be found."

The seventh cranial nerve, motor nerve of muscles of expression of the face, arises from a nucleus in the pons, the fibres passing towards the floor of the ventricle, curving around the nucleus of the sixth nerve, and emerging with the eighth (acoustic) nerve, between the olive and restiform body and with the auditory nerve enters the internal auditory meatus of the petrous portion of the temporal bone. Shortly before or just after entering the internal auditory meatus the geniculate ganglion is formed. The facial nerve after entering the internal auditory foramen traverses the bony canal called the aqueduct of Fallopius and issues from the stylomastoid foramen through a short course into the parotid gland, emerging upon the face just under the lobe of the ear, dividing into many branches to the face muscle. In its path through the aqueduct of Fallopius the facial gives off the branch to the stapedius muscle and is joined by the chordatympani nerve carrying taste fibres from the anterior two thirds of the tongue, and secretory fibres to that region. It should not be forgotten that in reality the facial is a mixed nerve conveying both motor and sensory fibres. According to Starr the facial nucleus is closely joined to many other cranial nerve nuclei by association fibres. This gives an anatomical basis for the many reflex and automatic acts in which the muscles of the head and face take part. In the acts of winking, breathing in motions attendant on sensations of sight, sound, taste and smell as well as vari-

ous bodily sensations, changes of the facial expression are constantly seen which are automatic. Mental states are also reflected in the face unconsciously and this is secured by an intimate association of facial nuclei and the centres in optic thalamus.

The muscles supplied by the facial are the platysma and buccinator, those of the external ear, and posterior surface of the digastric and and stylohyoid. Its chordatympani branch is the nerve of taste for the anterior part of the tongue, it is also a vasodilator nerve of the submaxillary and sublingual glands and its tympanic branch supplies the stapedius muscle.

The facial muscles supplied by the seventh nerve act upon the angle of the mouth especially those that elevate it, on the eyelids, especially the lower, elevating the latter and assisting in closure of the eye, also on the forehead enabling the brow to be wrinkled and the eyebrow raised.

Markowski and others have found parenchymatous degeneration from the geniculate ganglion downward to the periphery. The peripheral branches contained many degenerated fibres and a few remaining globules of myelin in a state of degeneration and many little fat cells. Some of the branches contained normal as well as degenerated nerve fibres and few degenerated fibres were found in the superficial petrosal and stapedius nerves. The findings were purely a degenerating neuritis without participation of the neurillema.

The disease may be occasioned by a variety of organic lesions and the cause together with the gravity of the condition depends upon the nature and site of the lesion. The paralysis may occur not only from a lesion of the nerve trunk itself but from interference with the nerve fibres at any point in the motor tract between the cortex and the facial nerve nucleus in the brain. Cortical paralyses produced by a lesion above the nucleus are less complete than is a lesion in the nerve itself and the eye can be partially closed, the eyebrows elevated and forehead wrinkled, the lower part of the face being the area chiefly affected. Hemiplegia is an example of this supranuclear palsy and the facial paralysis is but one of the symptoms displayed. Paralyses coming from a lesion in the facial nucleus in the pons are known as nuclear lesions. In these paralyses, the whole face is usually involved, the sixth and eighth cranial nerves may be affected and bulbar and other symptoms of basal involvement are usually shown. If the eighth nerve is involved with the facial there will be vertigo present. Isolated nuclear paralyses suggest syphilis and diphtheria. Of interest to the otologist especially, inflammation of the geniculate ganglion alone manifests itself by an herpetic eruption in the external auditory canal and outer ear. Many unexplanable pains of the ear, neuralgic in character, without any apparent lesion of the membrani tympani or adjacent structures, can be due to geniculate ganglion involvement and these may be the first symptoms of a facial palsy.

The diagnosis of the location of a lesion in the course of the nerve itself is not difficult. When in the course of the nerve the electrical reactions are lost, and when the lesion is central, the reactions are retained. If the nerve is affected at a point where the branch to the stapedius is given off, ear symptoms of tinnitus and hyperacusis are present. If the nerve is involved in the Fallopian canal where it is joined by the chordatympani there is loss of taste in the anterior two thirds of the tongue. This involvement of taste does not occur if the lesion is close to the exit of the facial from its bony canal. The typical complete Bell's palsy is that produced by lesions below the points at which the chordatympani nerve joins and taste and ear are not involved.

Lesions within the cranial cavity which produce facial paralysis are basilar meningitis, abscess, softening, hemorrhage, tumors, or exostoses at the base of the brain, syphilis or aneurysms in this location and any cases of intracranial tension.

In the Fallopian canal facial paralysis occurs in hemorrhage or inflammation, caries of the petrous portion of the temporal bone, acute and chronic otitis media, tumors in this region, fractures of the temporal bone, syphilitic lesions located here and it has been reported to occur from impacted wax in the external auditory canal. In cases of basal fracture besides the facial paralysis the eighth cranial and petrosal nerves are affected.

After the exit of the facial nerve from the skull, palsy has been noted in childbirth, with or without the use of instruments, glandular disease at the angle of the jaw, parotitis and surgical trauma.

Not infrequently, facial nerve palsy has accompanied infantile paralysis. It is to be noted also that recovery of function in the facial nerve has followed this disorder. In a few instances it is congenital and it has followed tonsillitis, diphtheria, scarlet fever, erysipelas, smallpox, anemia, alcoholism, typhoid fever, herpes, tetanus, influenza, tuberculosis, and occurred after the use of chromic acid in the mastoid bone. Oppenheim tells of bringing on a Bell's palsy by applying ice to a patient of his who at the time had tonsillitis. Infrequently, bilateral facial paralysis occurs and De Castro is the authority for the statement that ninety-five per cent. of these bilateral cases are syphilitic in origin. Also bilateral paralysis occurs occasionally in multiple neuritis. In a small number of cases of Bell's palsy the cause is supposed to be impossible to ascertain. One attack of facial paralysis predisposes the patient to another seizure and the disease happens more often in adult life between the second and fourth decades. In seven per cent. of the cases there are recurrences and in adults the same percentage is due to otitis media. Bell's palsy is found in females twice as frequently as in males, and occurs slightly more often during the warm months of the year than during the cold, as out of 139 cases reported by Leiner, seventy-nine occurred between the months of April and September.

The facial nerve is more often affected after its exit from the skull, either as simple neuritis, surgical or that occurring spontaneously in acute or chronic otitis media, the latter more often in children. In infancy owing to congenital clefts in the osseous formation there is greater danger in infantile otitis of peripheral paralysis of the facial nerve than in otitis media of the adult. The paralysis, however, in infancy is slight and disappears in a few days or weeks. That following acute inflammation of the middle ear in the adult is of infrequent occurrence but follows more often chronic suppurative otitis media. When the facial nerve becomes involved

from the ear, it is either an inflammatory neuritis or occurs from pressure upon the nerve from exudation either in the Fallopian canal or middle ear. As caries of the bony wall may take place even in the acute stage, the nerve may become paralyzed early in the course of the ear disease. The nerve has been found postmortem lying free in the tympanic cavity surrounded by pus and yet no symptom of involvement of the facial noted in life. From this observation one would conclude that compression either in the bony canal of the aqueduct or a blocked middle ear is the importnat factor in paralysis occurring during otitis media.

Treatment of facial paralysis as a sequel of otitis is directed to the ear, if there is absence of mastoid signs, by promoting free drainage incision, if drum be intact or only a small opening present. If paralysis persists in spite of free drainage, electricity and massage should be employed. Paralysis of the facial can resolve without mastoid operation as Jones reports a case of facial paralysis in acute otitis, recovery taking place in twenty-five days by treating middle ear conditions alone. Paralysis of the facial nerve is a cardinal indication for operation if the mastoid bone is involved, but the prognosis for restoration of function is not good. Voss, however, reports relieving facial paralysis of several months' duration by opening the mastoid and cleaning the antrum of hyperemic spongy tissue.

Surgical operations on the mastoid bone, especially where the radical operation is performed, are responsible for most of the operative cases of facial palsy due to either partial or complete section of the nerve, or the effects of shock or by localized edema or reactive processes in the contiguous tissue. If the paralysis is from the latter two causes recovery will take place. In children, owing to the small development of the mastoid process, the facial nerve lies superficially and consequently extreme care must be used in the young in performing even the simple mastoid opening, when drainage from the antrum only is sought. Also in the removal of large glands in the neck in children the nerve has been severed and extreme caution must be exercised to avoid injury in this operation. During the radical mastoid operation the nerve is frequently injured in the removal of the bridge between the antrum and middle ear, also in attempting to lower the posterior bony wall of the external auditory canal, to the level of the horizontal semicircular canal and in, curetting in the region of the superior internal wall of the attic.

The question of personal appearance is of the greatest importance, because all patients, and especially those who are young, are conscious of the immobile, masklike expression of the face. When the lesion is outside the skull all muscles of expression are affected except levator palpabrarum together with posterior surface of digastric and stylohyoid. Besides being unable to express themselves emotionally, there is difficulty in eating, drinking, talking and control of lips. The angle of the mouth drops and the ala nasi on the paralyzed side cannot be distended as on the healthy side. Drooling from the mouth occurs and there is troublesome lacrymation especially in the wind and cold.

Lacrymation is present because of the involvement of the orbicularis palpebrarum, the punctum no longer being held against the globe, consequently the tears can no longer make their way into the lacrymal canal but overflow the cheek. Neither winking or closing the eye is possible. Taste and smell are affected in some cases. There may be pain preceding paralysis in the ear and face with twitching of the muscles; and some deafness. After the attack, tinnitus and hyperacusis may be present. This unusual acuteness of hearing and the tinnitus are due to tension of the drum membrane from paralysis of the stapedius muscle. In the majority of cases the paralysis develops in a few hours and the face remains completely paralyzed for several weeks. Full recovery takes weeks or months and in a few cases the condition becomes permanent. Dana's observations show that Bell's palsy lasts from three to five months, mild cases recovering in one month. Secondary contraction of the muscles supervenes in about two months after the paralysis begins and there may be also twitchings and spasms of the muscles very annoying to the patient. If the patient does not recover from the disease the electrical irritability of the muscles gradually diminishes and is finally abolished.

In cases where the lesion is at the location of the geniculate ganglion the symptoms are herpes of the ear canal and pain and cutaneous anesthesia—Hunt's syndrome.

The prognosis of facial paralysis depends on the site and character of the lesion. The majority of cases clear up because they are cases of simple neuritis and therefore the more distal the nerve involved, the better the prognosis.

Congenital facial paralysis, if the result of failure of development of the nerve and muscles in the medulla, obviously will not recover. Lesions of the upper neurone affecting the brain or those on the surface of the brain are not likely to recover spontaneously. Partial recovery only may be expected in some cases and in cases where secondary contraction has taken place no recovery is to be expected. According to observations noted in cases of facial paralysis persisting, only slight recovery is made after four years. In postoperative cases, no recovery is to be expected if the nerve fibres have actually been severed. In cases also as a sequel to operation where it is not known whether actual severance is present, if the case is not showing improvement in six weeks, recovery is not likely. In operative or nonoperative cases if the reaction of degeneration be present which comes on after a couple of weeks, then a guarded prognosis should be made, as recovery may be a matter of some months, or not at all. However, the presence of electrical response is always a hopeful sign. Operation after several months' duration of the palsy may be thought of. This contemplates an anastamosis of the facial with the hypoglossal or the facial with the spinal accessory, but the result gained is questionable.

My attention was first called to the possibility of the infectious nature of facial paralysis by the quick recovery of a patient in one case following drainage of an antrum and in another by the prompt recovery from the disease following removal of infected tonsils. The response in these cases from removal of foci of infection was so prompt that I immediately

looked up the literature on the subject and found that one author had already reported four cases of facial paralysis, where the same results had been obtained on removal of infected points. Dabney's paper published in April is so far as I know the first to call attention to the infective nature of Bell's palsy.

CASE REPORTS[1]

Case I.—Male, sixty-four years of age, presented himself on August 11, 1925, complaining of pain and muffled tones in right ear for a few days. A small quantity of cerumen was removed from the canal at this time but the lumen of the canal had not been closed with the wax. Previous history negative. Three days later he returned with a right sided Bell's palsy with tinnitus which he had just noticed that morning upon arising. This patient presented no nervous disease symptoms. His main complaint outside of the facial deformity was that he could not keep his false teeth in position as he could not move his lips or mouth without the upper plate falling down and consequently he could not eat. He was referred to Dr. J. E. McCorvie, an internist of this city, for general examination and the following report was given.

"Patient on arising had noticed the right eye felt peculiar and his daughter stated to him that the eye 'looked funny.' Patient is a stockily built man, weighing 177 pounds, with blood pressure 196 systolic and 96 diastolic. Pupils and eye movements normal. Paralysis of the right facial nerve present, evidenced by lack of movement of the forehead, angle of mouth, and inability to close the eye on that side. Could not detect the taste of salt on the right half of tongue anteriorly. Heart enlarged, being four by eleven centimetres. Abdomen and genitalia negative. Knee jerks slightly reduced.

Urine and blood Wassermann examination negative. Blood hemoglobin 90 per cent., red blood cells 4,656,000, white blood cells 9400 per c. m. Temperature and pulse normal. Dr. McCorvie put the patient under general treatment as to diet and living on account of elevated blood pressure, and informed the patient that facial paralysis usually clears up but takes weeks to months to do so."

On September 1st, patient returned to me because of pain in right ear and along the region of the sternocleidomastoid muscle. He informed me that because of these pains he had, since August 11th. been compelled to apply heat several times during the night. The palsy was present exactly as when the patient was first seen. On examination the external ear, canal and drum were normal and no tenderness over the mastoid region was found. Hearing was normal. Transillumination of the antrum showed dark left antrum and x ray picture verified diagnosis of chronic left side antral disease and in this case known as a silent maxillary antrum. Nasal examination revealed slight amount of pus in the lower nares and in the region of the middle turbinate. Suction brought out a large quantity of thick greenish yellow pus from the left nares. The following day improvement was noted in the palsy and complete function of the nerve followed in four days. The nasal discharge became lessened in amount but continued in spite of daily treatment. After three weeks' trial of local treatment puncture of the antrum under the lower turbinate was made and irrigation every few days for two weeks until discharge ceased.

Case III.—I did not see this patient and the case occurred in the practice of Dr. F. M. F. Meixner who kindly gave me the history and to whom I am greatly indebted for the report of the case.

Female, aged twenty-four. General history and examination negative. No nervous disease symptoms. On June 27, 1925, she had an attack of acute follicular tonsillitis manifested by sore throat, nausea, delirium and pains in the neck; temperature 102°. This attack lasted ten days accompanied by swelling of the glands of the neck and some socalled rheumatic pains in the feet and wrists. On July 27th, she awakened from her sleep and found her face was "crooked," as she expressed it. Dr. Meixner found a facial paralysis on the left side accompanied by tinnitus in that ear. Taste was not involved. Treatment to the tonsils and local applications to the face together with galvanism was instituted. Continuation of this treatment for one week brought some recovery of function in the muscles about the mouth. Tonsils were cryptic with exudation of pus on pressure and the pillars were markedly injected. On account of the unsatisfactory progress of the case, advice to have tonsils removed, was given. Tonsillectomy was performed August 10th. There was immediate improvement during the week following operation and the patient was discharged as cured a month later.

Dabney's cases, one occurring from an infected antrum, two from infected teeth and the fourth from infection in the tonsils, were as follows:

Case I.—Male. Palsy attributed to "exposure to draft of air while overheated." Patient had an acute empyema of antrum and tonsillitis. In this case irrigation of antrum started restoration of function of nerve in thirty-six hours and complete recovery in ten days.

Case II.—Male. One attack of palsy five years before and both of these seizures attributed to exposure to cold. Removal of infected tonsils started nerve function in two days and complete recovery in two weeks.

Case III.—Male. Second attack of facial paralysis in six months, attributed to exposure to cold. Recovery to nearly normal in three months. Fifteen months later another attack for which an infected tooth was extracted and complete and permanent cure resulted.

Case IV.—Female. Facial palsy attributed to draft of cold air. A root infection of tooth was responsible and complete recovery followed extraction of tooth in ten days.

Dabney demonstrates by these cases that the cures are not coincidental because he points out that any line of treatment was inefficacious by the older methods. With all methods of treatment used heretofore it was a matter generally of months and by surgical intervention now definite cure is a matter of days.

He also reminds us that fundus lesions of the eye showing exudate and effects of infection, sixty per cent. are due to apical tooth abscess, twenty-five per

[1]The report of Case II was omitted for lack of space. It will be included in the author's reprints.

cent. to diseased tonsils, ten per cent. to nasal sinus diseases, and five per cent. due to foci scattered through the rest of the body, gallbladder, genitourinary and intestinal tracts.

His conclusion that "there is a definite connection or presence of infection in cases of Bell's palsy and that every case will show some focus of infection in the head or body and that this infection is the true cause of every case of facial paralysis," seems to be well founded and from my own observations I heartily concur with these views. There undoubtedly will be within the near future, reports of many cases of Bell's palsy where removal of infective foci will bring timely amelioration of symptoms and effect a permanent cure of the disease. I believe verification by ample clinical evidence will be made of the assumption that facial paralysis, of the Bell's palsy type, is a simple neuritis, infective in origin in every case.

A bibliography will appear in the reprints.

Amnesia Following Encephalitis Lethargica*

ALEXANDER STERLING, M.D.

Philadelphia, Pa.

Case.—Mr. S. S., fireman engineer, forty-two years of age, weight 190 pounds, height five feet six inches, married nineteen years. He has one living son eighteen years old. The patient called at the office Saturday night, September 12th, complaining of severe headache and some dizziness of one day's duration. He had some prodromal symptoms for the last seven to ten days, viz., malaise, fever, loss of appetite, and on September 11th a severe nosebleed. All of these he tried to fight off as an ordinary cold. His temperature was 103.8°, pulse 100, but there were no other clinical symptoms.

He was ordered to go home and stay in bed. The next day his temperature dropped to 100°, but the severity of the headache still persisted. On the third day the family noticed that he was delirious at intervals, at times apathetic, stubborn, and irrational. On the fourth day he seemed to be slow in answering questions, generally indifferent, and his delirium was more pronounced.

When it was suggested that he be removed to a hospital for further treatment he showed no interest whatever. The working diagnosis at that time was either influenza or typhoid infection.

He was placed in the men's 4-B ward of the Samaritan Hospital, Tuesday, September 15th. On admission his temperature was 103°. He slept most of the time. When aroused and asked as to his condition he complained of a headache and abdominal pain, but otherwise he was in a constant sleep, rather hard to arouse, answered questions slowly, and most of the time irrational. There were pin point pupils, but no meningeal symptoms, no ptosis and no paralysis. Heart, lungs, urine, reflexes, were all normal. With the development of the above mentioned symptoms, the diagnosis of encephalitis lethargica was selfevident.

Dr. W. Egbert Robertson saw the patient on the fourth day of his illness. He confirmed the diagnosis of encephalitis lethargica and suggested that the patient be given a trial of spinal fluid by injection every twelve hours for three doses.

Dr. Peters made an ophthalmological examination and could not find any diplopia or any other abnormalities.

The patient lay in bed sound asleep, snoring all the time. The snoring was getting louder day by day and he could be aroused only after some effort, and that only for a few seconds. When asked to open his eyes or to stick out his tongue he would do so. He would also make an attempt to answer some questions and would go to sleep while talking incoherently.

At times, especially during the first week, he was restless and would remove his gown. On many occasions he would get out of bed and urinate on the floor, and the nurses would have to put him back into the bed, and were obliged to strap him down until the services of day and night nurses were procured. He would often lie very still, with his eyes wide open staring into space, picking at his bed clothing. For a few days he had a twitching of his right hand and the right side of his face.

Respirations were short and rapid, forty to fifty a minute. Beginning on the fourth day of his illness Cheyne-Stokes respirations gradually began to develop which were getting more and more pronounced, lasting for three weeks.

The patient had difficult and painful urination. In the second week of his illness he voided little for two days. There was some distention of the bladder which perhaps caused the abdominal distress.

He was in a lethargic state for twenty-eight days. At times he snored and at times the sleep was very quiet. With all this he was able to speak and answer questions when aroused, or upon awakening, but this would last for only a few seconds.

Nourishment was difficult. However, two special nurses managed to push a great deal of liquid food into him every hour. Once he almost choked on a mouthful of food, falling asleep while in the act of swallowing.

He had involuntary movements all the time, even at the time of his release from the hospital. A striking peculiarity was an extreme dryness of the skin and the mucous membranes, although at times he had profuse sweats lasting from one to two hours, so that a change of bed clothing was necessary.

On the eleventh or twelfth day a glandular swelling appeared between the angle of the lower jaw and the ear on both sides. It was very painful to the touch and was probably responsible for the twitching of the facial muscles which was noticeable after the appearance of the glandular swelling.

*Read before Samaritan Hospital Medical Staff.

During the third and fourth weeks he had some rigidity of the neck, twitching of the extremities and very pronounced Cheyne-Stokes respirations. The prognosis appeared to be extremely grave.

COURSE OF TEMPERATURE

For the first and second day after his admission the temperature stood between 103° and 100°. For the following nine days the temperature ran between 102° and 100°. From the eleventh day to the fifteenth the temperature was between 99° and 98°. On the sixteenth day the temperature rose to 102°, and went down to normal in two days. This rise in temperature was possibly due to an infection of a subcutaneous injection. For the remainder (three or four weeks) the temperature was normal.

LABORATORY FINDINGS

The Widal reaction was negative. The urine was negative. Blood counts were as follows:

	September 16, 1925	*September* 30, 1925
Red blood cells.....	5,150,000	4,000,000
White blood cells	10,150	13,000
Polymorphonuclears	70	74
Small lymphocytes	17	18
Large lymphocytes	1	5
Mononuclears	3	1
Transitionals	2	2
Polymorphous eosinophiles	1	0
Polymorphous basophiles..	0	0

Wassermann, negative
Spinal sugar, .036 per cent.
Spinal globulin, 3+

SPINAL PUNCTURE

On the third day a spinal puncture was made for diagnostic and treatment purposes. Sixty c. c. of fluid was withdrawn under very high pressure. This fluid was injected into the gluteal muscles as suggested by Dr. Robertson. A second lumbar puncture was made and thirty c. c. of fluid was withdrawn under normal pressure with negative laboratory findings, therefore, no further lumbar punctures were made.

RECOVERY AND FURTHER DEVELOPMENTS

One night at the beginning of the fifth week the patient suddenly woke up and began to talk to the nurse about his wife, son, and family troubles. He also expressed the desire to go to work the next day.

From that time on he began to be quite awake at times. For the first week of his recovery he did not talk, except on the one occasion as stated, although he was awake at intervals for an hour at a time. In the second week of his recovery phase he began to talk a great deal incoherently. The periods of awakening were longer every day, and ordinarily he would appear as a man normally recuperating from a severe illness. He also began to sit up in bed and feed himself.

Symptoms of amnesia were evident at the sixth week. The man didn't know anybody by name; didn't know anything about his past or present; couldn't remember names, even of his immediate family; couldn't remember faces of visitors. He didn't know that he was in a hospital; he didn't know where he worked; he didn't have any shame or fear, in other words, his actions and behavior were similar to an infant one year old. He would have involuntary movements in bed, or go out of bed naked, unless watched by the nurses. With all this he knew his own name and could read newspapers and magazines, but he did not know what he was reading.

The nurses were instructed to train him, to teach him names, but it was all without any impression, even up to the time of his release. He would always make an attempt at conversation but it was always illogical and incoherent. He did not have any hallucinations or delusions. He was not violent. When wheeled out on the porch on the rolling chair the scenery and sights did not have any effect upon his memory. In other words, his mind was absolutely blank. Mentally he was not recuperating as well as physically.

TREATMENT

The first few days sedatives were necessary to relieve the restlessness and delirium. To reduce the temperature quinine urea hydrochloride in five grain doses was given every three or four hours, also large doses of potassium citrate, until the temperature reached 100°.

In the third and fourth weeks when collapse was threatening, digitalis, in ten and fifteen m. doses by mouth, was used several times a day in conjunction with caffeine citrate five gr. intravenously twice daily, and six gr. of camphor in oil were used in the gluteal region every four hours. For a few days aromatic spirits of ammonia was also administered, one dram every three hours.

At the suggestion of Dr. Bochroch the patient was given hot packs once daily for a few days, but this had to be discontinued because he did not react well.

In addition to the symptomatic treatments mentioned, a few other drugs were used, for the purpose of ascertaining their value in encephalitis lethargica. Stock ampoules of thirty-one gr. of sodium iodide in twenty c. c. distilled water were given intravenously every day for one week. It did not seem to make any difference, however. We stopped the iodides and administered neoarsphenamine; nine tenths grams were given every day for four days, with no effect.

An attempt was made to use salicylates intravenously, but no further intravenous medication was possible because of the collapse and damaged veins resulting from the neosalvarsan. However, twenty grains of sodium salicylate were given four times daily, which was continued up to the time of his release in conjunction with large doses of iodides and urotropin, alternately.

COMMENT

Encephalitis lethargica seems to be a selflimited infectious disease. While no specifics are known as yet, we merely had to resort to plain common sense symptomatic treatment, such as forced feeding; sedatives or stimulation were necessary as the occasion demanded. On looking over the patient's chart it seems that his recuperation coincided with the administration of large doses of sodium salicylate after a week's duration. His entire loss of memory and his infantile mind and behavior were among the striking peculiarities following this case of encephalitis lethargica.

1531 North Sixth Street.

Historical Medicine

Dioscorides and Hydrophobia*

HONORABLE WILLIAM RENWICK RIDDELL, LL.D., F.B.S., Edin., Etc.,
Toronto, Canada

The most celebrated of all the works of the ancients on materia medica is the *Peri Hules Iatrikes* (concerning materia medica) of Dioscorides.

Dioscorides (1) was born in Anazarbus in Cilicia and flourished apparently about the time of Nero in the second and third quarters of the First Century, A. D.

His work is substantially a herbal though there are a number of mineral and animal substances also mentioned and described; and it more than held its own for sixteen or seventeen hundred years. It cannot, indeed, boast of scientific or logical arrangement, the description given of plants when any description is given—for in many cases we have only the name or names—is generally defective, and sometimes contradictory or unintelligible. He falls far short in many respects of Theophrastus (2) of Erasos four centuries before; he was, however, writing a practical not a scientific treatise. For his times, it was reasonably exhaustive, describing, as it does, seven hundred plants, more than ninety minerals and one hundred and sixty-eight animal substances, not far from one thousand in all.

It has been made a matter of reproach that he ascribes too many virtues to one and the same substance; but that is the case with practically all herbalists—for example in the well known herbal of Nicholas Culpeper (3), the author frequently fills a quarto page with his enthusiastic enumeration of the virtues of an English plant.

At the present time the chief value of Dioscorides' elaborate treatise is historical as showing the kind and extent of materia medica knowledge in his day. There are five books of undoubted general authenticity, although there are probably a number of interpolations in them. A sixth book on Alexipharmics and a seventh on Theriaca (4) are added. The authenticity of these has been doubted but without much real ground for the doubt.

Of course the work was translated into Latin and printed—the best edition is said to be that of Sprengel in Kühn's Collection of Greek Physicians, Leipsic, 1829; but I have found an earlier edition wholly satisfactory, and, for an amateur at least, more interesting. The celebrated Joannes Ruellius (5) translated it into Latin and it was published in quarto form at Frankfort in 1543, under the editorship of Dr. Walter H. Ryff (6) who added many valuable and illuminating notes, the Scholia of Joannes Lonicerus (7) with Greek, Latin, Hebrew and German nomenclature being added—this is the edition I use.

The fact that Dioscorides attributes to one and the same plant many virtues has already been mentioned: this, of course, implies that for the same therapeutic effect any one of many plants is effective. For example, I have counted about seventy-five plants which are relied on to counteract the bites of venomous serpents, while there are literally hundreds of diuretics, laxatives and emmenagogues, cholagogues, vulneraries and styptics.

Some of the effects are at least interesting, e. g., if anyone chews anchusa and spits in a serpent's mouth, he will kill it; if one wear an amulet of spina alba, it is said it will drive away serpents—so will calaminth, peucedanum, cedrus and the stone gagates; while the juice of old elms mixed with anise and wine and rubbed on the threshold will keep them out, and "they say" lychnis placed near them at once renders them torpid and inert; "they say," too, that serpents cannot harm deer which eat elaphobos.

Witchcraft is kept away by branches of the rhamnus placed in the windows and the plague by sativa angelica; if children eat, roasted, "the mice that run around the house," it will cure slobbering—"if you dissect young swallows as soon as they are hatched, in a waxing moon, you will find in their belly two stones, one particolored, the other white—these not being allowed to touch the ground but tied in calf's hide or deerskin to the arm or neck will be of much assistance to epileptics and will often cure them at once." That is not the only wonderful thing about young swallows, for "some say that if young swallows are blinded the mothers will restore their sight by the application of the herb chelidonium." "Theophrastus says that if anyone puts pumice stone into a pot of boiling wine, the heat is at once abated." "The little worm from the heads of dipsacum or Venus' lip tied in a little sac to neck or arm is helpful as a remedy in quartan fevers," and "they say, that if anyone carries a polemonia root, he will not be bitten by a serpent, or, if he is, it will do him no harm"—this will make it less wonderful that the plant if chewed relieves toothache. In these post-O. T. A. and posteighteenth amendment days, it may be well to know that if the seats be sprinkled with water from the sacra herba, "banquets become more joyous."

It is well known that "medical men use mandragora when there is need of knife or cautery;" but it is not so well known that there is so much poison in the taxus of southern France (gallia narbonensis) that it injures and very often kills those who sleep under it—or *phyteuma aut leontopodium ad amatoria convenire et prodesse.* "Take a hair of the dog that bit you"—"the mus auraneus dissected and applied extracts the poison of its own bite" and canine urine helps in dog bites; and if psyllium, fleawort, is growing in a house, fleas cannot remain (8).

There are enumerated seventeen plants good for the toothache and eighteen for hydrophobia.

Hydrophobia which is the subject of this paper, Dioscorides treats of at length in his sixth book, of which Chapter XXXV, *Signa rabiosi canis & demorsorum ab eo,* I here translate as literally as the idioms of the two languages permit.

*Read before the University of Toronto Medical Society.

CHAPTER XXXV

SYMPTOMS OF THE RABID DOG AND OF THOSE BITTEN BY HIM

We have begun with the bite of a rabid dog because that animal is usually domestic and is more frequently attacked by and dies of rabies: consequently it is difficult to avoid it, and so there is great danger for man unless he uses many precautions.

The dog is generally carried into rabies by very great heat—although sometimes as many receive it through cold weather. The rabid animal avoids drink and food, much frothy phlegm (9) flows from nostrils and mouth, he looks savage and more gloomy than usual, he everywhere attacks every living creature without barking and bites all whether man or beast, familiar or strange. There follows no immediate injury except the pain from the wound; but later on, that disease which from fear of water is called by the Greek word "hydrophobia" appears.

It begins with tension of the nerves (10), rubor of the whole body particularly of the face, accompanied by perspiration and a sort of languor; some avoid the glare of day, others without any pain find difficulty in drinking. There are some, too, who bark like a dog and bite those they meet, thereby affecting them with the like disease. Of all who have had this disease, we have never seen a single individual escape death. We have, indeed, read of one here and there who escaped—at all events, Eudemus (11) asserts that a certain man survived. Some say that Themiso (12) being bitten was attacked by this disease and escaped; but others say that he was professionally attending a friend who had hydrophobia and that through the sympathetic concord of their natures he himself contracted a like affection; but afterwards after much suffering, he survived. This is a most malignant disease from which before they were attacked by it, we have saved many and we have known of many who have been saved by other physicians.

Then follows:

CHAPTER XXXVI

REMEDIA DEMORSORUM A CANE RABIOSO

Treatment of those bitten by a rabid dog.

There are two methods of treatment, one, general to be used in all bites of poisonous animals, the other, particular, and especially for those who are bitten by mad dogs; this for some is of the utmost value, but for others useless, especially for those bitten a long time before.

We shall first explain this latter treatment and then go rapidly through the general method.

It is necessary, then, to cremate river crabs (13) in branches of the white vine and, triturating the ash as fine as possible, keep it on hand, and also keep on hand gentian root, powdered and sifted; then whenever anyone is bitten by a mad dog, let two spoonfuls of the crabshell ash and one of the gentian be put in four cupfuls of pure wine and drunk like gruel four times a day.

This is the treatment to be followed if the patient has just been bitten; but if two or three days have elapsed from the bite we recommend three times the weight in addition.

This is the best treatment for those bitten by rabid dogs; it is sufficient alone in most cases and may be employed with confidence. But that we may protect the rest against imminent peril, there is no reason why the other methods should not be employed. And it would be far better for a patient even if he had confidence in the one, to suffer the excruciating pain of medicaments rather than to run into danger through neglect and indifference.

In the case of those bitten by a rabid dog, larger wounds are not so much to be feared as the smaller and those which are like small ulcers of the skin, as the blood coming copiously from a larger wound can carry with it some of the poisonous fluid, which does not happen in the smaller wound. In smaller wounds, it is necessary to draw back the surrounding flesh, to pare the lips with a sharp scalpel and seizing the flesh with hamulus or vulsella (14), to amputate it. In every case, the parts around the wound are to be scarified, so that there may be a more copious flow of the blood and thus prevent the poison insinuating itself into the members. Cupping assists in this treatment as thereby the power of the poison is drawn out. Around the poisonous wound, cauterization is the speediest help because as fire is more effective in its powers than all else, at the same time that it dominates the virus by its force and the pain goes no deeper than the iron, at that same time the part which has felt the fire furnishes no ordinary foundation for future treatment, the ulceration continuing to drip for a longer time. From the time that crusts begin to form, care must be taken lest the lips of the ulcer close and form a cicatrix; and if possible the ulcerations and foul wounds threatening inflammation should be kept off for a long and definite time.

The best topical application for these is a salsamentum (15) and ground field garlic and onion and its juice particularly what is called Cyrenian or Median or Parthian onion; wheat ground or unground is to be applied if the wounds gape by deep effusion.....

If, as often happens, cicatrices close before the time set, they do harm and require an operation; for it is proper to open them and pare the flesh around with a scalpel or apply the actual cautery again. When the time set has passed, the wound is to be brought to a cicatrix and the surrounding parts treated with a plaster of salt and not long after with a sinapism.

CHAPTER XXXVII

RATIO UICTUS IN MORSU RABIOSI CANIS

In the following Chapter XXXVII, *Ratio uictus in morsu rabiosi canis,* after recommending wine, raisin wine and milk for ordinary drink, onions, garlic and leeks as food, theriaca mithridate (16) or mixed with eupatorium and aromatics as medicine, the author continues:

It is well to know that fear of water does not set in at any fixed and definite time; for the most part, in those who neglect to take proper treatment, the attack is deferred to the fortieth day, some are attacked even after half a year; in one case which was brought to our knowledge, the fear of water appeared after a year—they say that some have been so attacked after seven years (17).

We have already given the treatment in the early stages. If the remedies we have referred to are not

applied, it is not worth while to pare the wound with the scalpel or to try cauterization for they cannot draw out what has now made its way in—there is no occasion, no use, in employing such treatment for in vain would the body be subjected to pain.

Another method of treatment presents itself—purging furnishes a great help since by powerful purgatives the habit of the body is wholly changed—the hiera which contains colocynth (18) and curdled milk both effects purging and also can master the poison. And food, reasonably pure wine, by which the force of the venom is much blunted, should be taken every day. Moreover, perspiration is to be forced before and even after meals and dropacisms (19) and sinapisms applied alternately over the whole body. But by far the most efficacious medicine is recognized to be hellebore which can be used with confidence not now and again only but very frequently before the fortieth day and even after that time. This remedy is said to have such power that those who have already begun to experience fear of water, if they take hellebore as soon as they feel the onset of the disease, at once are saved. No man can ever save those who are actually seized.

In the Scholium to this chapter it is pointed out that no less an authority than Galen himself (20) gives a perfectly satisfactory treatment for hydrophobia—he should not, however, receive full credit for it as he learned it from his fellow citizen and preceptor, Aeschrion (21).

Galen says: Gather river crabs in the summer time after the rising of the Dogstar, when the sun is entering the constellation Leo on the eighteenth day of the moon: bake them alive in a crucible of copper until they are so far calcined as to be easily comminuted and ground to powder. Of this powder let the patient take one spoonful a day in water if he begin immediately after the bite or two spoonfuls if he does not begin till some days after—this to continue for forty days.

Or mix ten parts of this crab powder with five of gentian and one of olibanum and give one spoonful per day to the patient in water. Apply to the wound, the following prescription:

℞ Picis Brutiæ	lb. j
Opoponacis	℥ iij
Aceti Acerrimi	Coch. ij.

Galen says that no man who made use of these medicaments had ever died. Paulus Aegineta (22) warns physicians not to let the wound heal too soon—some by treating the wound closed it prematurely when the hydrophobia did not speedily appear and that was the reason that although the fear of water did not appear at once, it came on afterwards. In most cases this symptom appears in about forty days but sometimes not till after six or even seven months.

No little attention was paid to the determination of the fact of rabies in the dog thought to be mad. Dioscorides does not furnish us with any pathognomonic indicia or any symptoms beyond what has already been set out: but later writers went much further and gave perfectly differentiating indicia. How to determine whether the dog that bit was rabid, Paulus Aegineta (22) shows very plainly and concisely—it was not, however, his own discovery, he took it from Oribasius (23). Here is the recipe. Carefully contused walnuts are to be applied to the wound for a day after the bite—then thrown to a cock or a hen. If it do not eat the nuts, starve it till it does; then, when it has eaten the nuts, if the dog was not rabid the bird will live, but if it was, the bird will die the next day.

Paulus thinks the fear of water in those suffering from hydrophobia is due to the immense dryness of their body which is antipathetic to what is wet: but some think this is due to their imagining that they see in the water the image of the dog which bit them.

Paulus adds that the persons here and there who have been cured of hydrophobia were not bitten by dogs but by other men: From this it may be understood that the poison of a mad dog is the very worst of all. Before they actually fell into fear of water, however, it is proved that many have been saved by treatment.

There were believed to be other prophylactic measures which might be taken. Dioscorides tells us that the liver of a dog affected with rabies, roasted and eaten by those he has bitten, is credited with saving them from hydrophobia—some, too, to prevent that fear of water, make use of the tooth called canine—taking this tooth from the dog which bit them and putting it in a little sack, they tie it on their arm as an amulet (24) (by the side of this, it is a mere trifle that an old liver long salted and taken in hydromel expels the secundæ). Galen does not agree as to the dog's liver—some, he says, using it lived but some died (25). In the treatment of the bite, Dioscorides gives a wide range. He advises the juice of lycium or pyxacantha taken as a potion with honey: a plaster of walnuts with onions, salt and honey applied to the abdomen: the flesh of the fish called mituli applied to the wound; a salt pickle of the fish called smarides or the salt sauce called garum from any fish: canine blood as a drink: canine urine with nitre topically applied: honey licked up or drunk: leaves of the plantago as a plaster: juice of leeks with honey drunk or applied: alyssum eaten as food: onions with honey and ground pepper as a lotion: the leaves of the cynoglossus with old hogs' lard (which by the way heal baldness as well as burns): leaves of the sambucus very tender and soft as a poultice (this also is good for burns): acida muria called by the Greeks, oxalme, injected into the wound hot and at once: Lemnian earth: nitre with asses' or hogs' fat and vinegar: ash of vine twigs as a wash with vinegar—I omit the medicines which are applicable to other bites than those of mad dogs specially (26). It is rather strange that Dioscorides does not make more of the alyssum which received its name from its supposed quality of heating or preventing canine madness—Galen is very strong that experience proved it equal to its name (27). It may fairly be said that if the assertions of Dioscorides and Galen as to the effect of their remedies were well founded, any one who died of hydrophobia had only himself to blame—but were they?

NOTES

1. The life of Pedanius Dioscorides is well written in Anthon's *Classical Dictionary*, Harper's, N. Y., 1871, pp. 448, 449; the author shows full appreciation of the work of Dioscorides and quotes largely from medical authorities. See also Bass: *History of Medicine*, Dr. Handerson's Edition, N. Y., 1889, p. 159, which places him A. D. 40-90, quite too early as I think.

2. Theophrastus of Erasus in the Island of Lesbos, born

382 B. C., a Peripatetic philosopher and teacher, the tutor of Erisistratus, the celebrated physician. His *Characters* is still well known. Of his many scientific works, the best is *Peri Aition Phutikon.* Of the Causes of Plants, a system of plant physiology. He wrote also on Law, Mineralogy, Metaphysics, etc. See Anthon, *op. cit.*, pp. 1231, 1232; Bass, *op. cit.*, p. 118.

3. Nicholas Culpeper's *English Physician and Complete Herbal*, first published in 1653, was frequently republished. A small 8 vo. edition of 1770 is useful; but the best edition is the sumptuous 4to of 1789, edited by the astrologer and Modern Freemason, Dr. E. Sibley. There are 413 plants described. For hydrophobia, he recommended allheal (heraclea), angelica, brawm, betony (this also against witchcraft), dwarf elder, eglantine, fig, garlic, hound's tongue, lungflower, mint nettles, pimpernel, moonwort, mad wort and a wonderful solar tincture. Culpeper (1616-1654) was an astrologer as well as a physician: the first edition of his famous book appeared in 1653; a new edition by Uriah Cole appeared in 1661: others in 1668, 1802 and 1803; the only edition of his complete works was edited by Dr. Gordon, and appeared in 1802. See 13 D. N. B., pp. 286, 287. Bass, *op. cit.*, p. 526.

4. Alexipharmics, medicines to prevent poisoning, prophylactics: theriaca—a medicine to cure poison, particularly that of beasts. But the words were often used indiscriminately.

5. Joannes Ruellius—Jean Ruelle (1474-1537), known to Bass, *op. cit.*, p. 435, and the *Bibliographia Britannica* as a Veterinary—*Veterinari Medicinæ Libri duo,* Paris, 1530; Basle, 1537.

6. Dr. Walter Herman Ryff (or Reiff), a physician and surgeon of Strassburg, about 1545, an eminent author of textbooks on anatomy and surgery and also brewing—the first anatomy in German. The present work shows much learning. See Bass, *op. cit.*, pp. 420, 429.

(*To be concluded*)

A Brief Summary of the Early Conceptions of Carcinosis

CHARLES GREENE CUMSTON, M.D.

Geneva, Switzerland

I assume that it is clear to most historians of medicine that the writers comprised in the Hippocratic collection were perfectly conversant with the nature of cancer, but only one mention is made of this, namely, that Phætusa, of Abdera, housekeeper to Pytheas, died of it (1). Yet in the *De morbis mulierum* the remark is made that women of sullen, depressed and melancholic temperament, as well as those suffering from uterine suppressions, are the subjects in which cancer is liable to occur, and the material cause is supposed to be an atrabilious leaven causing fermentation of the humors as well as aberration of the menstrual blood. Cough and abdominal disturbances are also referred to as factors in the cause of cancer and when the morbid process is not congenital it does not develop before the age of puberty.

Next we come to Galen (2), Celsus (3), Aretios (4), and the majority of the writers of antiquity who mostly accept the same opinion. They wrote quite exact descriptions of the disease but these varied according to the type of case, so that they cannot be comprised under a single pathological heading. Their etiology was of course governed by bile and atrabile.

Galen remarks that cancerous processes are derived from a thick viscous humor, gradually increasing in amount, and as he invariably finds fault with the medical profession in general, he does not lose the opportunity to state that all this is frequently the mistakes of physicians who strongly constrict or cool erysipelas or inflammatory processes.

Celsus supposes that the cause of cancer resides in a morbid state of the liver or spleen and points out that it is more prone to develop in the upper parts of the body.

Lastly, let it be said that Paulus Ægineta, who flourished several centuries later, assumes that the origin of cancer is to be sought for in the atrabile, hence it is usually corrosive in type. The disease may occur anywhere in the body, but its favorite sites are the uterus and female breasts (5).

Some nine centuries after Paulus we come to Ambroise Paré, who again takes up the subject and regardless of this long lapse of time we find this great surgeon indulging in the same theories of corrosive and malignant humors. Let me quote his words: *"La cause antecédent du chancre provient d'une manière de vivre, produisant un sang épais, mélancolique et limoneux"* which rendered into modern English would read: "The etiological factor of cancer is to be found in the way of living (of the subject) which will produce a thick, atrabilious and turbid blood." And again he says: *"Tout chancre est quasi incurable ou trés-difficile à guérir ou que, de tout son genre, est une tres mauvaise maladie, qui est ladrerie particulière."* (Every case of cancer is practically incurable, or at least very difficult to cure, because all forms are bad and represent a peculiar type of leprosy.)

Dionis, a famous surgeon of the eighteenth century, whose work on operative surgery is one of the most advanced for the time it was written, supposed that the cause of cancer was a coagulating acid that could be separated from the fluids composing a viscous, muddy blood. In the first volume of the *Mémoires de l'Academie de Chirurgie* is to be found a paper by Faget on cancer of the breast; the writer states that in his opinion cancerous growths result from thickened lymph which becomes converted into a corrosive sanious fluid. Many other eminent practitioners of the epoch also regarded cancer as due to some disturbance of the lymphatic system. On the other hand, Hévin, a contemporary of Dionis, objected to these opinions on the ground that these morbid productions are generally slow in growth and he favors the supposition that the origin of malignant neoplasms is to be found in a peculiar disturbance of the vessels of the lymph nodes. Then Ledrau published his paper on cancer in which he says that the lymph is the cause, quite independently of traumata and the cessation of menstruation which are so frequently invoked in the etiology of this affection.

At a later date, Pelletan maintained that cancer resulted from a thickening or coagulation of the lymph which stagnated in the part involved, while Gendron, rejecting the acrid leaven of Hippocrates,

thought that the origin of cancer was a congestion of one or several glands which progressively became indurated and finally scirrhous.

One of the most extravagant theories in respect to the origin of cancer was put forward at this time by Crawford, who maintained that the disease was due to a gas derived from the liver, of the nature of sulphuretted hydrogen and a substance which he supposed to be ammonia. Hence cancer was quite similar to gangrene, or a putrefactive process.

The celebrated John Hunter even went so far as to explain the development of cancerous processes to a globular shaped worm which he called "cancerous hydatid," and the great pathologist, carried away by his enthusiasm, described three kinds, namely, aqueous or sanguineous, gelatinous and bloody. Burns contradicted Hunter's hypothesis and stated that in all the cancerous tissues submitted by him to careful examination he had never discovered a parasite.

The famous clinician Stahl attributed cancer to a certain type of acid or putrid corruption, while Helvetius supposed the process due to coagulation of a few drops of morbid humor collected in an irritated lymph node. In Lieutaud's interesting book, *Précis de la Médecine Pratique* (6), we find that this distinguished physician attributes cancer in women to a melancholic humor developing at about the age of forty-five to fifty, while some seventy-five years later Richerand upheld the theory of concrete matter circulating in the lymphatics and nodes. At about the same time Sir Charles Bell in his book on ulcers denied the existence of an acrid fluid circulating in the humors as the cause of malignant disease, maintaining the only factor in the production of cancer is external trauma which gives rise in these circumstances to the quite acrid matter of cancer.

So far we have been dealing with suppositions, usually fantastic, and served in no way to the advancement of our knowledge of the etiology of cancer. We will now enter upon another phase of hypotheses but this time founded on experimental researches, and the first observer to be mentioned is Ponteau who, in 1760, published his book entitled *Recherches sur le vice cancéreux* (7). He admits two principal factors in the production of cancer, an external and an internal. An example of the former is a blow upon the parts involved which results in rupture of the bloodvessels and ecchymosis. The collection of blood becomes fluidified and acrid irritating the nerve fibres bathed in it; this gives rise to a small tumor which gradually acquires hardness.

In his *Dissertatio de cancro,* published in 1774, Peyrilhe (8) denies the theory of a primary cancerous diathesis. According to his way of thinking there is a certain spontaneous movement which, when once arising in a glandular concretion, only ceases when the mass of extravasated humors has become transformed into a putrid, acrid and corrosive ichor. As late as the year 1832, Sabatier maintained that cancerous manifestations were frequently the result of milk stagnating in the breast or to traumata, but that more usually they were the effect of an internal disposition developing at the approach of the menopause. Already in 1787 Selle was unable to decide whether or not cancer was a purely local process or depended upon a peculiar virus preexisting in the humors of the organism.

I am unable to refrain from referring to Roux, of Paris, in some detail, because from the modern viewpoint he puts forward some propositions that are not to be disdained even in our enlightened days. I quote: "Cancer is invariably preceded by some organic change of which it constitutes a special manner of degeneration."

"Cancer, an always identical affection, invariably the same, is quite unknown in so far as its nature is concerned."

"Although cancer at its onset involves only a small portion of the tissues (parts) it nevertheless extends and in its progress involves many other and different parts (of the body) which are not ordinarily primarily affected by it."

At about the same time that these judicious remarks were made—we are referring to the early part of the last century—Bayle had expressed the idea that cancer was a primary local lesion of a peculiar nature, and that if, in the same subject, it was combined with other types of organic degeneration of the tissues. This was no proof of a transformation, but rather a mere coincidence. According to another eminent medical personage of the same epoch, namely Marc Antoine Petit, there were three etiological factors each of which gave rise to three kinds of cancer respectively, namely: 1, traumata, functional disturbances during nursing and irregular menstruation; 2, the menopause, and 3, scrofula, the last named being the most frequent cause.

I must not overlook a rather rare little book by Fearon (9), entitled *A Treatise on Cancer,* in which the author, following the teachings of Boerhaave, regarded inflammation of the glandular structures of the female breast as a frequent cause of malignant disease.

As to statistics, it may be interesting to note that Terrier (10) in *Observations sur le Cancer,* published in 1806, states that ten women are smitten to one male; that the nature of cancer is unknown; that it is a local affection only in principle and in many instances is a general process.

Briefly put, up to the year 1812, only two theories reigned in respect to the etiology of cancer: 1. Cancer is due to a morbid state of the humors; there exists a preexisting general infection—otherwise, a cancerous diathesis. 2. There is no specific virus circulating in the blood. Cancer is a purely local process in principle and does not give rise to a cancerous diathesis unless a suppurative process progressively becomes acrid.

Then Laënnec, Andral, Cruveilhier, Lebert and Velpeau showed that cancer was primarily a local process, and finally cell pathology appeared upon the scene with Virchow in Germany, and Charles Robin in France, and opened up the road to the modern conceptions of this formidable scourge of humanity.

Editorial Articles

MALARIA AND GENERAL PARALYSIS

Some years ago, indeed so far back as 1887, Dr. Wagner-Jauregg, of Vienna, began to treat general paralysis by artificially induced fever. Erysipelas, tuberculin, dead streptococci and proteid were all tested on subjects of general paresis for a time. The theory is that if a patient's blood is heated to a certain point the germ of paresis is attenuated or destroyed. The experiments with typhoid germs and tuberculin were of only quite moderate success because these induced a fever which it was difficult to control. Wagner-Jauregg in 1917 substituted malaria and according to reports chiefly from Austria and Germany has met with encouraging success from this mode of treatment.

According to Dr. Alexander Pilcz, professor of psychiatry and neurology in the University of Vienna, who writes on the subject in the *Lancet,* January 6, 1923, the method of procedure is as follows: A patient is selected who suffers from tertian malaria, not tropical malaria, and who has not been treated with quinine. During an attack of fever two c. c. of blood are taken from the patient by venous puncture and injected beneath the skin of the paralytic patient's back. After one week or two weeks on the average the first attack takes place; the temperature rises to 40° C. and over. After some ten or twelve attacks the malaria is checked by quinine. During the first three or four days, 0.5 gm. quinine sulphate is given twice a day for three or four days and then once daily for two weeks; at the same time a course of neosalvarsan is begun, with intravenous injections once a week, commencing with 0.3 gm. and working up to 0.6 gm. Dr. Pilcz says that best results are given by cases with the maniacal affections and by those of simple demency. Generally remission does not immediately follow treatment; it develops gradually, finally becoming permanent.

The method may be employed not only in cases of general paralysis but also in tabes and in other forms of neurosyphilis; in disseminated sclerosis also, it is stated that good results have been obtained. Further, it is asserted that this treatment should be applied not only when general paralysis is manifest but also much earlier in all cases of secondary syphilis.

Dr. Gerstman has written a book which has been published recently in which he asserts that this method has been a conspicuous success and cites some hundreds of cases in which recovery, partial or complete, has resulted from the treatment. In the Verdun Hospital for the Insane near Montreal the same treatment is said to have been followed with success a short time ago. But while in countries other than Austria and Germany the treatment has been applied only tentatively and on a comparatively few subjects, in Austria and Germany treatment has been done on a large scale and, as said before, it is affirmed with great success. Of course, time is the sole proof of the permanency of the cure. On the other hand, many of the patients treated in Austria and Germany have been free from their former disabling physical and mental symptoms for a considerable time, so that even if such results are obtained, it would seem that a trial of the treatment is well worth while.

MORPHOLOGY IN RELATION TO RHEUMATISM AND OTHER JOINT AFFECTIONS

Chronic, or socalled chronic diseases, perhaps occupy the attention of the medical profession more than any of the other ills of mankind, for the reason that they are more obvious and troublesome now than ever previously. Of all the maladies which afflict the human race none is more persistently prevalent, causes a greater amount of invalidity, and in certain respects is more deadly in its aftereffects than rheumatism. In the issue of the JOURNAL for May 20, 1925, Dr. F. G. Crookshank discusses the morphology of this affection in an original manner. His proposition in his own words is, that the parts and tissues most easily and most often affected by environmental and accidental stresses are those which, judged by the standards of comparative morphology, are distinctly "inferior," that is to say they are those which are the less "evolved" when compared with their like, and which exhibit reversionary characters or at any rate preserve embryonic or infantile features, and he carries this argument to its logical conclusions according to his point of view.

The less, indeed, any external part or member conforms to the Greek standard the more it approaches the standards of primitive races and the anthropoid apes; and the more likely this member and the organs correlated with it in function are to break down under strain.

In the case of rheumatism and the rheumatoid affections it is contended that the affected joints and correlated structures are so often markedly inferior, that there is justification in asserting a correlation between morphological inferiority and liability to certain joint affections. Rheumatism regarded from this aspect attacks those who from imperfect evolution of certain joints and correlated structures and who are

thereby not protected against such ouslaughts as are those whose evolution has reached a higher stage or a higher degree of perfection.

The hands, hips and lumbosacral spines, the parts attacked by arthritis, belong frequently to the Mongolian type or Mongol Orang type, more frequently than otherwise. However, the conformation and distinguishing characteristics of the hands, hips and lumbosacral spines have been dealt with at some length in Crookshank's book, *The Mongol in Our Midst,* published recently, and as said before his suggestion is that this delayed or imperfect development in a morphological sense has rendered the individual of this type more prone to arthritic seizures in those parts of the body where this imperfect development is most evident. Crookshank's article is highly stimulating and refreshing both from its unconventionality and from the instructive way in which his thesis is propounded. Also it may be said to have a distinctly practical bearing, as if it be allowed that this lack of development is a factor of importance in the causation of arthritis, it should be of value in diagnosis and treatment, especially of a preventive nature. In the course of the article attention is drawn to a point of rare interest, namely, that the French believe firmly that "chronic arthritics" possess what is termed the "arthritic diathesis." Moreover, Crookshank has the impression that those who suffer from acute rheumatism are persons in whom the "lacunar system," the lymphatic and serous complex, offers less resistance than is normal to certain infections. Confessedly, much has to be learned of rheumatism and allied affections, if such terms are permissible, and any ideas which tend to throw fresh light upon their obscure features. Crookshank's article is thus illuminating and possesses further the rare merit of not being tedious.

TUBERCULOSIS CURES

Are there cures for tuberculosis? The Sphalinger Semm and what is termed the sanocrysin or gold treatment of tuberculosis have been in the limelight recently. The Sphalinger treatment has many adherents in Great Britain and in Canada. It has been announced that Dr. Godfrey, the Minister for Labor and Health in Ontario, who has just returned from the International Labor Conference in Geneva, was so greatly impressed with the Sphalinger treatment that he intended to introduce the method into Ontario. As for the gold treatment, it is reported from London that Dr. Faber, of Copenhagen, informed the London National Association for the Prevention of Tuberculosis which met a short time ago, that seven months of tests of sanocrysin of forty-two cases of chronic pulmonary tuberculosis resulted in eight being clinically cured; seventeen others showed considerable improvement, nine were unimproved and six showed a tendency for the disease to spread.

Professor Cummins, of Cardiff, stated that six cases under his supervision showed strong evidence of reduction of bacilli under sanocrysin. Without exactly laying oneself open to the charge of being a "doubting Thomas" it may be remarked that there have been a very large number of reputed cures for tuberculosis, none of which have fulfilled the claims made for them. Indeed, several of them have done more harm than good by arousing false hopes and by inducing persons in an advanced stage of tuberculosis to take long journeys and to expend much money, with the result that they have died more quickly by far than they would have died otherwise. It is continually being reported that a cure for one or other disease has been discovered and it can be said that if one per cent. of these reports had proved to be true there would be many ways of curing all the diseases known.

It is known that if diphtheria antitoxin in the proper doses is given in time it is practically a cure. It is hoped that the scarlet fever antitoxin which is now on trial will be equally successful. As a matter of fact there are few definite cures. No doubt the proper and timely use of drugs has saved many lives. But such drugs assist Nature to tide over a certain period in order to give the body time to bring its own defensive powers into action. That is why drugs should be given only on the advice of the family physician. He knows the drug that should be used, when it should be used, and how much of it should be given.

It may be stated that there is no cure known for tuberculosis, that is no medicinal cure. At the present time successful treatment of pulmonary tuberculosis consists in early diagnosis and treatment which signifies rest, fresh air, plenty of sunshine and a sufficiency of suitable food. Advanced cases, in which the contagious element plays its part, should be segregated for the sake of the community at large.

Although it is absolutely just that the Sphalinger treatment and the gold treatment should be given fair and extended trials, because they are vouched for by medical men of reputation, it is not wise to refer to them as cures until the evidence in their favor is very much more convincing than it is at present. In this connection the recent experiments concerning the rôle of calcium in the causation of tuberculosis is interesting. French physicians some time ago contended that tuberculosis was characterized by decalcification on the excretion of an excessive quantity of calcium and that the rational treatment was to supply the system with calcium as far as was possible. At the present time these views are supported by other

investigators, notably by Dr. Boyd Orr of the Rowett Research Institute, Aberdeen, and appears to be a commonsense mode of treatment.

IODINE THERAPY

The value of the mineral salts and, perhaps, of iodine, in particular, is the outstanding feature of the most recent therapy. For some time vitamines held the field and the mineral salts were overshadowed. Matters are now on a more rational basis and while all due respect is paid to the vitamines, the other chemical elements of the human body are regarded with the consideration which is their due. For this more correct estimation of the mineral salts credit is chiefly owing to Dr. Orr, director of the Rowett Institute, Aberdeen. During the past few months discussion has been especially rife on the subject of goitre, which has been found to be very prevalent in this country as well as in other countries. Endemic or subthyroidal goitre is indeed widespread and negative evidence seems to have proved conclusively that it is brought about by a lack of iodine in the system. Knowledge of the endocrine glands and their exact functions is still in the early stages and perhaps the only one of these glands of which precise knowledge does exist is the thyroid. It is thought by some to be the director probably of the endocrine system, and if it gets out of order the other glands are apt to get out of gear and ill health is the consequence.

Instability of the thyroid gland manifests itself very frequently in the form of goitre both of a hypothyroidal and hyperthyroidal nature. As said before, it has been demonstrated by negative evidence that hypothyroidal goitre is owing to a deficiency of iodine in the system, because it has been proved that if in such cases iodine in proper doses be given that the thyroid will resume its functions and normal health will be the result. But Plummer in March, 1922, showed that iodine exerts beneficial effects in the treatment of exophthalmic goitre. Now Dr. Arnold S. Jackson, of Madison, Wisconsin, in the *Lancet*, April 11, 1925, corroborates and supplements the findings of Plummer by stating that in a series of sixty-three cases operated upon in his clinic between October, 1922, and October, 1924, there were neither surgical mortalities nor medical deaths, and these results were because iodine was used orally. Not only has Plummer's discovery revolutionized our ideas concerning the effect of iodine in exophthalmic goitre but has provided a means of combating successfully the dreaded clinical postoperative hyperthyroidism. It is not claimed that iodine cures hyperthyroidism but it is declared to have a most remarkable effect on the condition. Within forty-eight hours after its ingestion there is a marked abatement of all the symptoms. The nervous, vascular and digestive systems are all favorably influenced and there is an average reduction of plus nineteen per cent. in the basal metabolic rate. It appears then that simple goitre may be prevented and treated successfully by the administration of iodine and that exophthalmic goitre is benefited by a similar procedure. Consequently both hyperthyroidism and hypothyroidism seem to be amenable more or less to iodine therapy. Although there are no precise data upon which to lay down definite rules as to iodine therapy in these conditions, the outlook is encouraging and with greater experience more light will be thrown on the subject. The future for iodine medication is full of promise, as instability of the thyroid and, perhaps, hypothyroidism especially, is responsible for or a factor in the causation and development of many diseases.

Also it may be noted that iodine medication not infrequently fails because iodide of potassium and other iodine preparations are not tolerated by all persons and their prolonged use is liable to upset the digestion in many cases. However, it appears to have been proved conclusively that a sufficiency of iodine in the system is essential to good health and that when there is a deficiency this lack must be supplied.

THE NATIONAL BOARD OF HEALTH

The National Board of Health, which was in existence for a brief period during the latter part of the nineteenth century, writes James A. Tobey (*Nation's Health*, January, 1926) represents an almost forgotten incident in the history of public health in the United States. The immediate cause of the creation of the board was the disastrous epidemic of yellow fever, which swept over this country, apparently from Cuba, in 1878, and was the worst visitation of this kind for a century. Although the epidemic was most prevalent in the South, all parts of the country were severely attacked. It is estimated that one hundred thousand persons were stricken and that twenty thousand died. The monetary loss to the country has been estimated as from one hundred to two hundred millions of dollars. It cost New Orleans alone about ten million dollars. So great a popular calamity was it that President Hayes said in his annual message: "The fearful spread of this pestilence has awakened a very general public sentiment in favor of national sanitary administration, which shall not only quarantine but have the sanitary supervision of internal commerce in times of epidemic and hold an advisory relation to the state and municipal health authorities, with power to deal with whatever endangers the public health and which the municipal and state health authorities are unable to regulate."

The subject of a national quarantine had been advocated and debated for many years. As early as

1796 an act reative to quarantine had been passed. This was repealed in 1799 by a new law which recognized the authority of the several states over quarantine matters, and primarily a state function it remained, until April 29, 1878, when an act was passed by Congress which empowered the Surgeon General of the Marine Hospital Service, with the aid of customs officers, to impose and enforce maritime quarantine in cooperation with state and municipal officials. The passage of this law was directly influenced and brought about by the discovery through a study of conditions that of eighty-eight epidemics of yellow fever from 1683 to 1878, seventy-seven had been definitely proven to have been introduced from foreign countries through commerce. The National Board of Health was created about a year after this first quarantine law, by an act of March 3, 1879; on June 2nd of the same year a new law was passed placing the enforcement of national quarantine, still in cooperation with the states, upon the National Board of Health, which was authorized to promulgate necessary rules and regulations for the purpose. The board was also directed to obtain and publish sanitary information from foreign and domestic sources. Half a million dollars was appropriated for this work.

The board originally consisted of eleven members, seven appointed by the President, three medical officers from the army, navy and marine hospital service, and one representative from the office of the attorney general. James L. Cabell, LL.D., was elected president and acted in that capacity throughout the existence of the board, although some of the other members were changed. The National Academy of Science was directed to assist the board and scientific aid was also obtained from the American Public Health Association which had been founded in 1852 by Dr. Stephen Smith, and of which Professor Cabell was president.

The board undertook and in many cases completed during its rather brief existence a number of important investigations and sanitary surveys which are valuable contributions to medical and sanitary science.

In the course of time, however, some of the southern states, led by Louisiana, made trouble on the basis that they did not consider quarantine to be national in scope. Interference with commerce in the interests of health, no matter how humanitarian or important, interfered with commercial profits, and the trouble grew. The National Board was blamed for instigating a quarantine against New Orleans, and was charged with extravagance and usurpation of power. Also, the emergency conditions due to epidemics were over and Congress began to lose interest. Although delegates from twelve of the states, including the trouble maker, Louisiana, sent an expression of confidence in the board's work to President Arthur, interest in political circles continued to wane, and the National Board of Health ceased to exist on February 15, 1893, when an act was passed granting additional powers and imposing additional duties on the Marine Hospital Service. This was the first real national quarantine law. An attempt was made in 1899 to reestablish the board but in vain.

The National Board of Health was a successful venture while it lasted, although its career was somewhat turbulent, due to the controversies instigated by certain states for commercial reasons. It forms a worth while precedent for future action.

ACUTE APPENDICITIS

In Great Britain appendicitis is a common complaint and apparently is increasing. At a meeting of the Liverpool Medical Institution held on March 18th last Mr. G. C. E. Simpson read a paper on acute appendicitis in which some extremely interesting and somewhat startling facts were brought out. He said in part, that from the Registrar-General's reports checked by his knowledge of a small town where he had been able to trace most of the cases of acute appendicitis during the past five years he had come to the conclusion that the incidence of the disease was about one case per one thousand of population per annum, with a mortality in cases treated surgically of about six per cent. According to Osler's *Medicine* 1901 cases treated on medical lines had a mortality of fourteen per cent. He suggested that this would be reduced to less than half if the general peritonitis and abscess cases were submitted to immediate operation and the rest treated on medical lines. In this opinion, with which opinion it may be said that many surgeons here and elsewhere are in agreement, he thought that the careful choice of the time of operation in later cases would give a reduction, apart from the reduction to be effected by earlier diagnosis.

As for himself he operated at once in all cases seen in the first two days, in cases seen later which were advancing, and, as a rule, on all children. He used the Ochsner method in doubtful or subsiding cases seen on the third day or later, and operated when they had subsided. These cases, however, must be kept under close observation, and intervention undertaken at once if signs of progression were seen. On these lines Mr. Simpson's results had been very successful. His mortality in the Northern Hospital during the past five years was only 2.5 per cent.

He concluded as the outcome of his experience and observations that the mortality of acute appendicitis could be lowered by judicious choice of the time to operate in cases not seen before the third day, but emphasized the need for the cases to be under strict observation and regulation. He considered that this would lead to all suspect cases of appendicitis being kept in the Fowler position and on water only while waiting the advent of the surgeon and that this and the opportunities given to students to see more of the symptoms of appendicitis through these patients being detained in the wards, would more than neutralize the ill effects from some doctors carrying out the treatment in the wrong cases and under wrong conditions.

Fig. 1.—Montefiore Hospital, showing Nurses' Home at extreme left.

Montefiore Hospital for Chronic Diseases

JACOB GOODFRIEND, Assistant General Superintendent
New York, N. Y.

Montefiore Hospital was established in 1884 under the name of Montefiore Home for Chronic Invalids. Its facilities for the proper care and treatment of chronic diseases were rather limited and the institution therefore functioned more or less as a "home," giving custodial care to those afflicted with incurable ailments. There has been a gradual change in the character of the institution to that of a hospital. In order to correct the impression that has prevailed in many quarters that the institution was chiefly a home for aged people, when as a matter of fact it is a hospital in every sense of the word, the name was changed more appropriately to describe the nature of the work we are doing.

The medical equipment covers every phase of diagnosis and treatment. Particularly noteworthy are the x ray, physiotherapy, dietetic, occupation therapy and medical photographic departments.

Patients requiring medical study for diagnosis or treatment, or skilled prolonged nursing care, are admitted to the main hospital buildings. Many are rehabilitated and discharged to their homes. Others, who require custodial care only and who are homeless, are transferred to the Schiff or custodial pavilion, which is designed particularly for their care.

There is a completely equipped research laboratory devoting its energies to the study of chronic diseases, as well as fully equipped cancer research and neuropathological laboratories.

The social service department gives assistance to patients and their dependents in their social and economic problems.

The first building occupied by the Montefiore Hospital was situated on the upper East Side of New York City and had accommodations for thirty patients. The need for expansion, however, manifested itself during the early years of its existence and its progress, as can be seen from the following table, was very rapid:

GROWTH OF BED CAPACITY

Hospital Building		*Hospital Building and Branch at Bedford Hills*	
1884	30 beds	1905	441 beds
1890	140 beds	1910	472 beds
1895	270 beds	1915	700 beds
1900	350 beds	1926	806 beds

The block plan and the following description indicate that the buildings are substantially of the pavilion system, in so far as the different buildings are separate and isolated for all practical purposes, but connected by covered corridors.

This group of buildings comprises the administration building, which contains the offices, living rooms of the medical staff, school room for the children, and meeting rooms in one half, and a private pavilion with accommodations for thirty patients in the other, on the ground floor of which are classroom, demonstration room and laboratory of the Nurses' Training School. The service building contains the power plant, kitchen, dining rooms, auditorium, receiving department, laundry and linen room. The synagogue has a seating capacity of three hundred, the basement of which is occupied as a general storeroom. The dormitories, with the workshops in the basement, can house one hundred and sixty employees.

PAVILIONS

The patients occupy four pavilions. The central pavilion is the largest and consists of four stories and basement. The enclosed roof is used as a medical photographic department. The east and west

pavilions consist of three stories and basement each. The south pavilion is a structure 340 feet in length with only two stories and basement. All buildings are connected by covered corridors. The wards units are sixty beds in the central pavilion, thirty beds in the east and west pavilions, and thirty-five beds in the south pavilion.

The central pavilion—An occupational work room

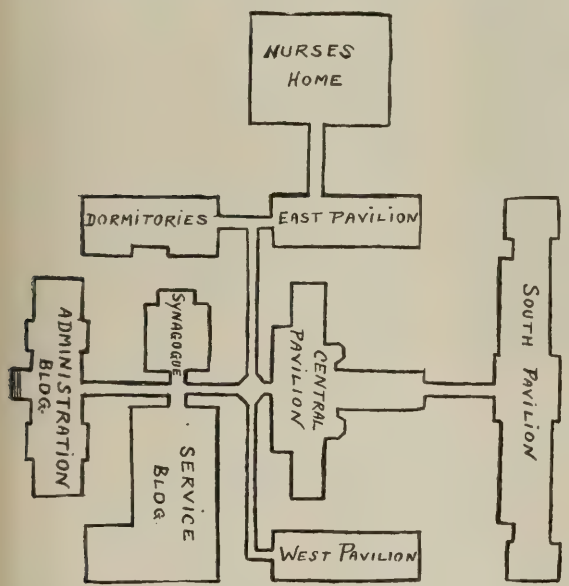

FIG. 2.—Block plan showing corridors connecting all buildings.

in charge of an efficient staff of instructors is provided for those of the inmates who can do a certain amount of therapeutic work; the number of hours of work is prescribed by the house staff. The occupation department and children's playroom are on the level of the cement walks and gardens, so that wheelchair patients and those who walk on crutches can enjoy the use of the grounds. The drug department, tailor and barber shops and patients' cooperative store (canteen) are also situated in the basement of the central pavilion.

The west or medical pavilion.—This pavilion has two floors for patients, with an elaborate electrocardiograph department on the second floor. The morgue, autopsy and funeral rooms and x ray department are in the basement. On the third floor the research laboratories are located, the roof being used for animal quarters.

The east pavilion.—There are two floors for surgical and orthopedic cases in this pavilion. In the basement are rooms for physiotherapy, comprising hydrotherapy, electrotherapy, baking apparatus and mechanotherapy (Zander machines). Two large operating rooms, dental department, and nurses' infirmary are on the third floor.

The south pavilion.—The more advanced cases of pulmonary tuberculosis are accommodated here; those in the incipient and second stages are sent to our sanatorium at Bedford Hills, N. Y., now caring for 220 such patients. Balconies extend over the entire south end of the building, and all rooms, including the recreation rooms, open out to these balconies, so that all beds can be moved out. The upper porch recedes about three feet so as not to obstruct the light in the rooms of the lower floor. Separate lawns are reserved for the tuberculosis patients.

The basement level of the buildings is used for deliveries, laundry trucks, etc. The main floor is intended for passenger traffic, i. e., for patients and employees; the next floor represents a roof garden, guarded by a railing, and being an open air connection to all the buildings, it serves the purpose of a fire escape.

The entire group of buildings is surrounded by a park sixty feet wide.

The hospital conducts a Training School for Nurses in which forty-five pupils are enrolled. The Nurses' Home accommodates seventy-five nurses.

The special diet kitchen prepares over one hundred diets for diabetics and other patients who require special foods.

The distinguishing feature of chronic disease, as the name implies, is its long duration. Most of our patients require months of treatment to achieve rehabilitation. Some are left nonprogressively disabled and still others become worse, the illness lasting many months and even years.

Four clinical divisions are maintained as follows:

	Beds Available		*Children*		
	Male	*Female*	*Boys*	*Girls*	*Totals*
Medical	61	60	11	13	145
Neurological ...	75	72	7	4	158
Tuberculosis (advanced stage)..	97	53	0	0	150
Surgical (including cancer and orthopedic) ...	65	62	7	4	138
	298	247	25	21	591

Chronic patients are here grouped in three classes according to the demands they make on the resources of the institution, as follows: Class A: Those in need

FIG. 3.—The first Montefiore Hospital, 1884, corner Eighty-fourth Street and Avenue A.

of active medical care for diagnosis and treatment. Class B: Those who need nursing care only. Class C: Those who are in need of custodial care only.

One can readily understand that patients do not remain in any one class indefinitely. A patient may be placed in Class A on admission, but show sufficient improvement in the course of a few months to be placed in Class C; while on the other hand, a patient in Class C (custodial) may become acutely

Fig. 4.—Occupation Therapy Department. Weaving Room.

ill which places him in Class A. There is provision in a separate building (Schiff pavilion) for sixty Class C patients who require no active medical care or treatment, but whose economic condition is such that they cannot be returned to their homes.

The Institution conducts four out patient clinics for those who do not require hospitalization, or patients discharged, whose progress it is desirable to observe for a time, namely,* cancer, cardiac, physiotherapy and diabetic.

The scientific application of water in the treatment of chronic disease, known as hydrotherapy, was first substantially recognized in this country by Dr. Simon Baruch, one of the first presidents of the medical board of the hospital. In 1893 this hospital was the only public institution in the country which possessed a complete outfit for hydrotherapy. We may justly claim for the institution the position of pioneer in this important and fruitful field. The hospital has kept pace with the rapid strides made, both in this country and abroad, in all branches of physiotherapy, with the result that we can today still regard with pride and satisfaction the fact that our equipment is as complete as any connected with a public institution in the country.

ACTIVITIES OF INSTITUTION

The activities of the institution are summarized in the following abstract from the statistical reports for 1925:

	Excluding private pavilion
Total number of patients treated in the Institution since its inception, October 26, 1884	30,000
Number of patients treated during the year	1,510
Patients discharged during the year	560
Deaths during the year	389
Days of care for the year.	205,067
Average length of stay:	
Tuberculous patients	95 days
Other chronic patients.	144 days
Schiff pavilion (custodial patients)	266 days
LABORATORY:	
Autopsies	85
Pathological examinations.	288
Chemical examinations	2,749
Bacteriological examinations	322
Serological examination	1,621
Basal metabolism	117
OPERATING ROOM:	
Major operations	72
Minor operations	282
Plaster casts	44
Anesthetics	61
Salvarsans	207
Nose and throat cases treated	484
Eye cases treated	449
X RAY DEPARTMENT:	
Hospital and clinic patients	2,271
RADIOTHERAPY DEPARTMENT:	
X ray treatments	1,629
Hospital and clinic Radium treatments	12
PHYSIOTHERAPY DEPARTMENT:	
Hydrotherapy treatments	5,029
Massages	7,953
Bakings	4,279
Electrotherapy treatments.	8,457
Mechanotherapy treatments	8,243
DENTAL DEPARTMENT:	
Patients treated (Comprising prophylactics, plates, fillings, extractions, cavity preparations and x rays)	2,892
ELECTROCARDIOGRAMS:	656
PHARMACY:	
Ward prescriptions	43,589
Clinic prescriptions	1,139
Employees' prescriptions	765
DAILY AVERAGE SCHOOL ATTENDANCE ....children	27
OCCUPATION THERAPY:	
Average daily number of patients employed in shop	29
Average daily number of patients employed in ward	60
DIETETIC DEPARTMENT:	
Average number of special diets a day	129
SOCIAL SERVICE DEPARTMENT:	
Visits to ward patients	2,980
Home visits	1,858
Other visits	854
PHOTOGRAPHIC DEPARTMENT:	
Plates	431
Prints	1,190
Lantern slides	151
Microphotographs	464

Fig. 5.—Physiotherapy Department. Mechanotherapy equipment.

News Items.

Boylston Prize.—It has been decided that no award of the Boylston prize of the Harvard University Medical School will be made this year.

Civil Service.—An assistant statistician is desired in the United States Public Health Service, entrance salary twenty-four hundred dollars. Applications should be sent to the Civil Service Commission by June 8th.

Dr. Morton Honored.—A tree has been planted in Honor Grove, Central Park, New York, and dedicated in the name of Dr. Rosalie Slaughter Morton, of New York, in recognition of national and international patriotic and humanitarian services.

Cutter Lectures.—Sir Arthur Newsholme of England delivered the Cutter lectures on preventive medicine at the Harvard Medical School. His subjects were Present Position of the Tuberculosis Problem and Remaining Problems in Maternity and Child Welfare.

Indian Medical Service Reorganized.—The Indian medical service has been reorganized with Dr. Marshall C. Guthrie, of the United States Public Health Service, appointed chief medical director. Four districts have been established, each with a medical director in charge.

Radium Spring.—Bad Brambach in Saxony, known as the Radium Spa because its waters have the highest radioactivity of any spring known today (more than two thousand Maché units), has discovered three new radiomineral springs that mean an additional supply of three hundred cubicmetres of mineral water a day with a radioactivity of more than five hundred Maché units. In order to cope with the yearly increase of visitors, a new Kurhaus, colonnades, and bathhouses have been erected, and new tennis courts for sportlovers have been laid out.

Dr. Davison Honored.—A dinner was recently given in Chicago in honor of Dr. Charles Davison, who has been appointed attending surgeon emeritus at the Cook County Hospital, after thirty-two years of continuous service on its staff. Dr. Davison is also emeritus professor of surgery of the Illinois College of Medicine. A portrait bust of him by Lorado Taft was presented to the College at the time of the dinner. The president of the University of Illinois, Dr. David J. Davis, dean of the College of Medicine, and Dr. Edward L. Heintz of Chicago were among the speakers.

Bureau of Medical Research.—A bill to establish a bureau of medical research in the department of the interior has been introduced by Representative Woodruff of Michigan. Its purpose would be the investigation of physiological processes, the devising of means for controlling bodily processes, and the determining of physical, chemical, and biological properties of materials when this would be useful medical knowledge. One hundred acres of ground near Washington would be bought, buildings erected at a cost of not more than one million dollars, a director appointed by the President at a salary of $15,000, an assistant at $10,000, and such other personnel provided as would be necessary.

Guggenheim Foundation.—Among the awards of the John Simon Guggenheim Memorial Foundation, established a year ago with a three million dollar fund by Mr. and Mrs. Simon Guggenheim, in memory of their son, is one of Dr. Harold Myers Marvin, assistant professor of medicine of Yale University. Dr. Marvin is appointed for research in the field of cardiovascular physiology in Sir Thomas Lewis's Laboratory at the University College Hospital, London, England.

Personal.—Dr. Charles C. Williamson, formerly director of the information service of the Rockefeller Foundation, is the new director of the libraries of Columbia Univeristy.

Dr. Jacob Sobel has received an appointment as attending pediatrist at the Hospital for Joint Diseases, New York.

Dr. William Howard Godsick and Dr. Irving Smiley have been appointed assistant attending gynecologists and obstetricians to the Lincoln Hospital, New York.

Dr. Benjamin Philip Watson, of the University of Edinburgh, has been appointed professor of midwifery and diseases of women in the College of Physicians and Surgeons, New York, and director of the Sloane Hospital for Women.

Dr. Abraham Kosseff has been appointed superintendent of Beth Moses Hospital, Brooklyn; he was formerly chief physician at Sing Sing.

Dr. William Calhoun Stirling, Jr., has received an appointment as associate professor of genitourinary surgery at Georgetown University Medical School, Washington, D. C.

Lieut. Col. Charles F. Craig, of the United States Army Medical Corps, has been appointed director of laboratories and of the department of clinical pathology and preventive medicine at the Army Medical School.

Dr. John A. Waggener, of Humboldt, Nebraska, has recently celebrated his fiftieth anniversary in the practice of medicine.

Dr. Myron A. Zacks has received an appointment as chief of the department of otolaryngology at the Northwestern General Hospital of Philadelphia.

Dr. Knud Faber, professor of internal medicine of the University of Copenhagen, recently spoke on Intestinal Origin of Pernicious Anemia, before the Harvard Medical School.

Dr. George A. Ulrich of Philadelphia has been appointed chief visiting obstetrician to Northwestern General Hospital.

Dr. Emanuel Libman of New York recently delivered two courses of lectures at the U. S. Veterans' Bureau Hospital at Oteen, North Carolina.

Dr. Thomas H. Haines has resigned as director of the division on mental deficiency of the National Committee for Mental Hygiene, in order to engage in private practice.

Dr. Henry F. Bean of Portsmouth, Ohio, has recently celebrated his fiftieth year in the practice of medicine.

Dr. Anthony J. Lanza, director of the National Health Council, has resigned to do group insurance and industrial hygiene work with the Metropolitan Life Insurance Company.

Gifts and Bequests.—By the will of Ella A. Rogers the New York Hospital received $50,000; the Lincoln Hospital and Home, and the Servants of Relief for Incurable Cancer each received $20,000, and the Home for Incurables, New York, received $10,000.

The New York Eye and Ear Infirmary received $5,000 by the will of the late Dr. Dwight W. Hunter as a memorial to his son.

The Mount Sinai Hospital, New York, the United Hebrew Charities, the Hebrew Benevolent and Orphan Asylum, each received $5,000; the Montefiore Home for Chronic Invalids received $2,000, and the Home for Aged and Infirm Hebrews received $1,000 by the will of the late Albert Lorsch.

By the will of the late Margaret Elizabeth Griffith the Manhattan Eye, Ear and Throat Hospital received $5,000, and the residuary estate, on the death of his sister, estimated at more than $900,000, to the Presbyterian Hospital, New York.

The will of the late Mrs. Harriet J. Sayre, of Southampton, Long Island, provides $3,000 for the Southampton Hospital, and $2,000 for the Greenport Hospital.

By the will of the late Columbus B. Rogers, and that of his daughter, Ella, recently deceased, the New York Hospital, New York, received $50,000; the Lincoln Hospital, New York, $25,000; the Servants for the Relief of Incurable Cancer, $25,000; St. Mark's Hospital, New York, $20,000; the Home for Incurable, New York, $10,000.

Society News and Notes.

Coming meetings of interest at the American Museum of Natural History are as follows: New York Microscopical Society evening of Friday, May 7th; Section of Biology of the New York Academy of Sciences, Monday, May 10th; and New York Microscopical Society, Friday, May 21st.

* * *

The thirteenth annual convention of the Society of Industrial Engineers will be held at Philadelphia, June 16th to 18th, with the Bellevue-Stratford Hotel as headquarters.

* * *

The fifth international Congress on Genetics will be held in Berlin in September, 1927. Prof. E. Bauer, president of the German Genetic Society, is chairman of the committee on arrangements.

* * *

At the meeting of the Section of Anthropology and Psychology of the New York Academy of Sciences, held in conjunction with the American Ethnological Society at the American Museum of Natural History on April 26th, the audience enjoyed a view of the motion picture film, *Moana,* taken in Samoa by Robert J. Flaherty to show the daily life of the world's most beautiful and fast vanishing people, the Polynesians.

* * *

The meeting of the Chicago Dental Society, held in that city January 27th to 29th, was the largest in the history of the society. Although the organization is primarily local in character, contributors to the program came from Iowa, Massachusetts, Georgia, Minnesota, Colorado and Louisiana.

* * *

The American Society for the Prevention of Cruelty to Animals offers a cash prize of $1,000 to the inventor of a nonslipping horseshoe. The announcement says that out of six hundred devices examined not one fills the bill. "Sharpshoeing" and calks are excluded from the contest as impracticable and unsatisfactory devices for city streets.

* * *

At the latest meeting of the Yorkville Medical Society, a hospital relief fund was created to aid needy members. The committee in charge consists of the following physicians: Samuel J. Druskin, A. Schoen, M. F. Goldberger, Peter M. Bisher, Benjamin Rosenbluth, L. Glassman, Harris Weinstein, Braham H. Golden, William Grossman, Maurice Meltzer, and Charles N. Gelber, chairman.

* * *

The Flatbush Medical Society has elected the following officers for 1926: President, Dr. Howard V. Merrill; vice-president, Dr. William Steinbugler; treasurer, Dr. C. E. Rynd; secretary, Dr. H. H. Patrie; associate secretary, Dr. Joseph G. Terrence.

* * *

The Association of Volunteers in Social Service, *Better Times Magazine,* City Recreation Committee, Federation of Institutions Caring for Protestants, United Hospital Fund, and Welfare Council of New York City, have all established new headquarters at 151 Fifth Avenue, New York.

* * *

The next meeting of the Philadelphia County Medical Society, which will take place on May 12, 1926, will be devoted to tuberculosis. Dr. S. Adolphus Knopf of New York will speak on Mental and Physical Rest in Pulmonary Tuberculosis, and Dr. Howard Lilienthal of New York will discuss Surgical Methods in the Treatment of Pulmonary Phthisis.

* * *

At the last annual convention of the American Stomatological Association, held at the New York Academy of Medicine on April 6, 1926, the following officers were reelected for the year 1926-1927: president, Dr. Weston D. Bayley, Philadelphia; president elect, Dr. George R. Satterlee, New York; first vice-president, Dr. George W. Mackenzie, Philadelphia; second vice-president, Dr. Oliver T. Osborne, New Haven; treasurer, Dr. Robert H. Rose, New York; recorder, E. B. Sardisty, New York; general secretary, Dr. Alfred J. Asgis, New York.

* * *

Dr. P. F. Armand-Delille, president of Grancher Society of Paris, organized for the prevention of tuberculosis among children, describes the work of the organization in the current issue of the *World's Health.* The society is conducted on the principle that tuberculosis is not a hereditary, but a purely contagious disease.

* * *

Dr. James F. Cooper, of New York City, was a speaker at the annual meeting of the Arizona State Medical Association held recently at Globe. His subject was Contraceptive Technic.

The Utah Pharmaceutical Association has compiled a list of "ten common sense and generally accepted rules of what to do in case of poisoning for a list of forty potent drugs," on the theory that, when poison has been taken, we should not have to search laboriously through a book, but should have immediate knowledge available. The list compiled by the Utah society is compact and occupies a small enough space to be hung conveniently on the wall or kept in the medicine cabinet.

* * *

Health and Empire is the title of the new journal of the British Social Hygiene Council which began publication in March. The articles in the first number are by such authorities as C. L. Burt, M.A., D.Sc.; T. Percy Nunn, M.A., D.Sc.; C. J. Bond, C.M.G., F.R.C.S.; Leonard Findlay, M.D., F.R.C.P.S.; and G. D. Knox. The new magazine will be published by Constable & Co., Ltd.

* * *

The Physicians' Square Club, composed of Master Masons, will celebrate its anniversary with a dance to be given at the Hotel Majestic, New York city, on the evening of May 6th, to which friends of members are invited.

* * *

The New York Pharmaceutical Conference, Inc., with offices at 1440 Broadway, New York City, consists of twenty-one recently affiliated associations of pharmacists in New York and surrounding counties. The object of the affiliation is to ensure a closer relationship with the medical profession.

* * *

The American Board of Stomatology was created at the last annual convention of the American Stomatological Association in order to facilitate matters in maintaining a standard of fitness for the practice of stomatology as a medical specialty during the transitory period. An examination will be held by the American Board of Stomatology in New York City on Thursday, April 21, 1927, at the New York Academy of Medicine, during the annual convention. This examining board will issue certificates of proficiency to those who qualify under the established standard and they will be admitted to the annual Stomatological Medical Register, which will contain a list of those practitioners who have qualified in accordance with the standard set by the American Board of Stomatology.

* * *

On the evening of Wednesday, May 19th, a combined meeting will be held in Philadelphia of the Section of Otology and the Section of Laryngology and Rhinology of the New York Academy of Medicine, with the Philadelphia Section of Otology and Laryngology. The program will be announced later.

* * *

The League of Red Cross Societies is arranging a Pan-American Red Cross conference to be held in Washington, D. C., May 25th to June 5th. Each Red Cross Society has been invited to bring, in a consultative capacity, representatives of the public health organizations of their respective governments. There is a likelihood of the participation of other organizations doing international work, such as the International Red Cross Committee in Geneva, the League of Nations, the Rockefeller Foundation, and the International Council of Nurses.

* * *

The American Stomatological Association has received an official communication from the Federazione Stomatologica Italiana, with headquarters in Bologna, Italy, heartily endorsing the work of the former organization in the United States in its endeavor to bring the science of dentistry into line as a branch of general medicine, and praising the work done in education along these lines by the Postgraduate School of Stomatology, chartered by the University of the State of New York, and supervised by the American Stomatological Association.

* * *

The general subjects for the various sessions of the American Health Congress to be held at Atlantic City, May 17th-22d, have been announced by the chairman of the special program committee, Dr. Haven Emerson, as follows: May 17th, dance; May 18th, forum session, training of sanitarians; May 19th, clinic on publicity, immunization, nutrition; May 20th, teaching of hygiene, pollution of water by industrial wastes, milk; May 21st, ideal health administration for large and small cities, qualifications and duties of health officers. Joint sessions of various organizations tentatively scheduled will be on venereal disease control, graphic presentation of public health nursing, and diphtheria immunization. Sessions of the congress itself have been planned for the evening of the seventeenth, the afternoons of the eighteenth and of the twentieth, and the evening of the twenty-first.

* * *

May meetings at the New York Academy of Medicine will include the following: the stated meeting of the Academy will take place on Thursday evening, May 6th, at 8:30, when the address of the evening will be by Dr. Bernard Sachs on the Mental and Moral Training of the Normal Child; Duties of Physician, Parent and Teacher; A Critical Analysis of Modern Trends and Doctrines; on Friday evening, May 7th, the Section of Surgery will meet, with presentation of cases by Dr. John H. Morris, Dr. Alan D. Smith, Dr. John H. Garlock, Dr. William F. Honan, Dr. Bradley L. Coley and Dr. Ralph Colp; Dr. Harvey B. Stone, of Baltimore, will read a paper on Intestinal Obstruction: the Clinical Application of Experimental Studies, and Dr. Frederick T. Van Beuren, Jr., will speak on the Use of Enterostomy in Acute Ileus; the Section of Neurology and Psychiatry will meet on Tuesday evening, May 11th, with case presentations by Dr. Irving J. Sands and Dr. William V. Cone, and papers by Dr. H. G. Wolff on Gastroduodenal Ulcers and Autonomic Imbalance, and Dr. L. Pierce Clark, a Further Contribution to the Psychology of the Essential Epileptic; Thursday evening, May 6th, the Section of Pediatrics with presentation of cases from the Babies' Hospital, Bellevue Hospital, Mt. Sinai Hospital, Nursery and Childs' Hospital, Presbyterian Hospital, Roosevelt Hospital, St. Luke's Hospital, St. Mary's Hospital, Vanderbilt Clinic, and Dr. Rudolph D. Moffett.

Book Reviews

BLOOD PRESSURE

Blood Pressure. High and Low. By Chester Tilton Stone, M.D. New York: Allen Ross & Company, 1925.

While not invariably accurate, this little book gives a readable and useful review of the facts concerning normal and abnormal blood pressures that are of interest and value to the layman. The advice to patients with high blood pressure is simple and sensible, with emphasis on general temperance in eating, drinking and living, and the author rides no hobbies. The necessity for health examinations and medical supervision is emphasized. Few would agree, however, that seventy per cent. of hypertensives can be cured, and that excess of salt is the chief cause of high blood pressure.

OCCUPATIONAL THERAPY IN MENTAL DISORDERS

Occupational Therapy for the Mentally and Nervously Ill. By Louis J. Haas. Milwaukee: The Bruce Publishing Company, 1925. Pp. 409.

The book is divided into two sections, the first a general discussion of the subject, and the second a treatment of the individual crafts as to their benefits and disadvantages. The history of occupational therapy shows that for a long time it has been considered valuable in treating mental disorders. The Egyptians probably realized the curative value of occupation as early as 2000 B.C. David knew what results to expect when he played on his harp before Saul. Galen wrote in 172 A.D., "Employment is Nature's best physician, and is essential to human happiness."

The author's underlying theory is that it is the first and chief mission of a department of occupational therapy to create a modified normal atmosphere in which the patient is to pass at least some of his time. Another chief tenet is the intensive study of every individual, and his tastes and idiosyncrasies, for, the author writes, "being busy is not necessarily therapeutic." Choice of crafts and their relative value are next treated, and the discussion illustrated by a chart. To summarize some of the conclusions on this phase of the subject, basketry is considered as best adapted to serve the majority of patients, because it is varied, but is classified as third from the viewpoint of tool requirement and safety. Weaving is said to be the safest, but holds ninth position from the viewpoint of service, as do also circular and tennis net loom work and tennis racket stringing, although the former is third in safety and the latter tenth.

From his experience in various institutions and organizations as instructor in occupational therapy, the writer has evolved three questions, all of which must be answered affirmatively if the craft in question is to be continued. These are: 1. Is it interesting work? 2. Can it be so presented and controlled that the reaction thereto is therapeutic? 3. Can the patient perform four fifths of all the work involved?

Chapters follow discussing the plans and construction of buildings and the various shops for conducting occupational therapy; the selection of equipment, tools and materials and their care; department organization, records, relation to the hospital, standards of work, and the reception of patients. After his description and evaluation in the second part of the book of the various crafts, the author gives an account of his own apparatus devised for bedside occupation, and a discussion of its use in the wards.

Mr. Haas has been for more than a decade director of men's therapeutic occupations at Bloomingdale Hospital at White Plains, N. Y., and has taught in various other institutions in the East, so he is well qualified and equipped to discuss his subject, which he does with comprehensiveness and detail.

The style of the book is simple and clear, and its make up attractive.

GASTRIC FUNCTION

Gastric Function in Health and Disease. By John A. Ryle, M.D., F.R.C.P. Oxford Medical Publication. London and New York: Oxford University Press, 1926.

In this important monograph Ryle has computed his clinical experience and experimental studies regarding gastric function in health and disease. He has made extensive use of the fractional method for determining the secretory function and agrees in most respects with Rehfuss. In reference to the sensory function Ryle emphasizes that gastric pain and referred pains of gastric disease are separate manifestations, and that the former is actually produced in the viscus. Gastric pains may be classified into those which develop shortly after taking food, and those which develop after a much longer interval, when the stomach is again becoming empty, immediate and delayed pain. Gastric pain persisting apart altogether from the act of eating can generally be traced to extragastric causes, or to an extension of gastric disease beyond its seat of origin.

The author stresses the necessity of using good judgment in making a diagnosis. The conception that a clinical syndrome commonly associated with a certain lesion, such as duodenal or gastric ulcer, may be closely or exactly reproduced by other forms of irritative lesions might seem at first to increase existing difficulties in differential diagnosis. At the same time such a conception clearly serves to explain the frequent lack of agreement between clinical opinion and the findings of the surgeon.

By broadening our outlook and paying greater attention to detail in the examination of cases most of the mistakes can be avoided. The book can be highly recommended as a useful addition to our medical literature.

SURGICAL CLINICS

The Surgical Clinics of North America, St. Louis Number, Volume V, Number 5, October, 1925. Philadelphia and London: W. B. Saunders Company.

The usually high standard of these Surgical Clinics has been maintained in this number. Sixteen clinics are given, the subjects including clinics on horseshoe kidney, osteomyelitis, bleeding myoma, ileocecal tuberculosis, clubfoot, fracture of the larynx and cholecystography. There are 114 illustrations of excellent quality. While there is nothing in this volume of unusual character, it is of high quality and an excellent addition to those of the series which have preceded it.

Medicoliterary Notes.

A dreamy eyed, shabbily dressed man, who a year ago was a builder's laborer, was presented by Lord Oxford and Asquith with the Hawthornden prize of one hundred pounds sterling for the best work of imaginative literature produced during the year by a writer under forty. He was Sean O'Casey, the Irish dramatist who leaped so suddenly into fame with two dramas—*Juno and the Paycock,* and the *Plough and the Stars.* In presenting the prize Lord Oxford described *Juno and the Paycock,* the work for which it was awarded, as "the most moving and impressive drama we have seen for ten, it may be twenty, years."—*N. Y. Times.*

* * *

In a report recently issued by Dr. Eleanore Conover, assistant director of the Hospital Information Bureau of the United Hospital Fund, it is shown that sixty of the 134 public and private hospitals in New York City have women superintendents, and that women act not only as nurses and nonprofessional workers, but also as trustees and managers. Of the institutions canvassed, twenty-six per cent. had women exclusively on their boards, and fifty per cent. men only. Of the hospital patients fifty-six per cent. are usually women.

* * *

A census of the orphanages in the United States taken recently has revealed the fact that only ten per cent. of the child inmates are orphans.

* * *

Footprints believed to be those of the earliest land vertebrate have been recently discovered in the Grand Canyon. They are supposed to have been made by the ancestor of the frog or salamander, which must have been much larger than his present day progeny, since the prints measure four inches in diameter and are an inch deep in the hardened, primeval mud. Plaster casts have been made of the foot prints, which are being studied at the National Museum of Natural History.

* * *

The Belgian War Office has recently ordered the abolition of the cavalry as a branch of the service which has outlived its usefulness. The Belgians contend that there is no field of war in which rifles and machine guns cannot rout the finest cavalry charge before the riders can get within damaging distance of the enemy.

* * *

One of McBride's recent publications of significance is James Branch Cabell's new novel, the first in three years, entitled the *Silver Stallion.* This, Mr. Cabell has announced, is the culminating romance of the cycle of Poictesme, but it stands third in the chronology, following *Figures of Earth* and preceding *Domnei,* and *Jurgen.*

* * *

In view of the widespread interest in the periodical medical examination, it is of interest to call attention to a labor-saving device for both examiner and subject, which has been designed and successfully used by Dr. J. Madison Taylor, of Philadelphia. This is the "preliminary history blank," to be made out by the patient or his family, and revised by the physician or specialist in any line. It forms an orderly record of all significant facts in a clinical history and the findings of previous advisors, and serves also as a basis for further or particularized examinations, directing attention to questions requiring special elucidation.

* * *

When the municipal authorities in several villages of the Austrian Tyrol levied a tax on every girl over twelve who had her hair bobbed, quoting St. Paul, I Corinthians XI, 15, to support their action, the local barbers' associations vigorously protested on the ground that this was interfering illegally with their trade. However, the mayors of the villages have so far turned deaf ears to the complaints of the barbers and the young Tyrolean beauties will have to chose between the bob and the tax.

* * *

What a Man Goes Through is the title of a recent publication from the Christopher Publishing House, Boston, by Dr. F. P. Millard. In spite of the book's rather ultra-popular and somewhat sentimental style, it contains a good many sensible and wholesome suggestions on the "art of living." Another publication of the same firm is entitled the *Law of Life* and *Human Health,* by G. R. Clements, LL.B., M.D. A foreword describes this work as "a book for the layman, the student of life, the health promoted, the doctor, the student of the soul, the religious worker, the minister, and the scientist,"—rather a large order! The text is full of health platitudes, interspersed with quotations from the Scriptures, popular poetry, and capitalized and italicized statements. The style reminds us somewhat of the old time circus broadside about the "Greatest Show on Earth!!!"

* * *

The few remaining snuff factories in Great Britain have recently closed their doors because there is no demand for the commodity which they manufactured and sold, according to the *Manchester Guardian.* The exsnuff makers blame the cigarette for the decline in the use of their commodity. In the days when smoking in the presence of ladies was not quite *au fait,* and was forbidden in many places, a pinch of snuff satisfied the desire for tobacco. The decline in the use of snuff began toward the last half of the last century and it grew feebler and feebler. There was little or no evidence of "Sir Plume of amber snuffbox justly vain" even half a century ago.

* * *

In view of the recent literary controversy which has raged over the book of poems by Natalia Crane, Brooklyn's girl poet, Merck & Co., manufacturing chemists of New York, have published in the January issue of Merck's Report a poem on Creolin which was sent to them by Natalia in 1923, when she was only ten years old.

* * *

One of McBride's early publications will be the translation of *A Brazilian Tenement,* a novel by one of that country's most popular authors, Aluizio Azvedo. It is described as presenting the life of a Brazilian community of the eighties, "a tenement housing a hundred families, in which blacks and whites mingle without distinction of race, the people simple as children in their mirth, and ruthless as beasts in their pursuit of food and love."

* * *

A valuable aid to physicians has been published in the form of a Digest and an Editorial Article on the Federal Narcotic Laws as They Apply to Doctors of Medicine, by the Los Angeles County Medical Association. While primarily intended for the use of physicians, the pamphlet is applicable also to dentists and to veterinarians.

* * *

The Department of Labor of the State of New York has recently issued as *Special Bulletin No.* 139 an analysis of 300 accidents in woodworking factories, with suggestions as to safe practice and suitable machine guards.

* * *

The transactions of the Twenty-third Annual Conference of State and Territorial Health Officers with the U. S. Public Health Service, held at Washington, June 1-2, 1925, has been issued as *Public Health Bulletin No.* 161 by the Surgeon General.

* * *

Mental Hygiene for January is a number of unusual interest. The table of contents is as follows: The Dynamics of the Relation of Physician and Patient, by William A. White, M.D.; Psychoanalysis as General Psychology, by Dr. Otto Rank of Vienna; The Kindergarten as a Mental Hygiene Agency, by Arnold Gesell, M.D.; Enuresis as a Psychological Problem, by Helen T. Woolley, Ph.D.; "What Can I Do with Johnny?" by Adeline E. Darrt; The Relation of Intelligence to Behavior, by Ira S. Wile, M.D.; Physical Findings in Problem Children, by William E. Carter, M.D.; The Significance of Physical Disease in Relation to Behavior Problems, by Edwin R. Eisler, M.D.; A Form of Psychogenic Tiredness, by K. M. Banham Bridges; Psychiatric Phases in Vocational Guidance, by Harry M. Tiebout, M.D.; Report on the Ninth International Prison Congress, London, 1925, by Bernard Glueck, M.D.; Community Service Activities of the Danville State Hospital, by J. Allen Jackson, M.D., and H. V. Pike, M.D.; Abolition of Mechanical Restraint at the Willard State Hospital, by John B. Chapin, M.D.; and A Study of the Waiting Lists of State Institutions for Defectives in Pennsylvania, by Florentine Hackbusch.

American Medical Association

Seventy-seventh Annual Meeting, Dallas, Texas, April 19-23, 1926

(*Continued from page* 534)

The Scientific Proceedings

We present below abstracts of some of the more important papers read at the various section meetings. The publication of these abstracts will be continued in future issues of the JOURNAL.

SECTION ON PHARMACOLOGY AND THERAPEUTICS

CHAIRMAN, DR. THOMAS ORDWAY, OF ALBANY, N. Y.
SECRETARY, DR. N. M. KEITH, OF ROCHESTER.

The Action of Hepatic Extract in Hypertension.—Dr. Ralph H. Major, of Kansas City, Mo., said that with the increase in life span during this generation there has been an increase in the prevalence of the diseases of middle age and after, prominent among which was arterial hypertension. High blood pressure had no uniform etiology and was probably invariably produced by the abnormal contraction of the arterioles. Such contractions may be due to several causes, and it is probable that certain poisons of metabolic origin may be concerned. The author found that methyl guanidine, a normal constituent of the urine, was capable of producing a marked and prolonged elevation in blood pressure in animals and in man. In a series of laboratory experiments the action was studied of various substances which lower the blood pressure produced by guanidine. Certain liver extracts were very potent in both producing and preventing such an experimental hypertension.

The liver extract with which they have been working was obtained by a process of alcoholic fractionation and has a nitrogen content of .001 per cent. The presence of histamine, choline, and peptone can be excluded with a reasonable degree of certainty. The liver extract produced no sharp fall in blood pressure such as these three substances produce, has little effect upon normal blood pressure, and is not toxic in very large doses. It produced no contraction of smooth muscle as does histamine, but on the contrary inhibited contractions due to histamine. No symptoms suggesting anaphylactic shock have been encountered. The author said that they had standardized the liver extract against guanidine and had taken as a temporary unit the amount of depressor substance necessary to neutralize 0.1 mg. of guanidine in an animal weighing 2.5 kilograms. During the past year approximately one hundred patients suffering from high blood pressure have been treated with this histamine and choline free preparation. These patients have been divided into three groups, those under observation in the hospital, those in the out patient department and private patients. Some of the most suggestive results have been obtained in the latter group, who represent a type of patient of intelligence and perseverance. This group also had the least evidence of arteriolar and kidney involvement. The treatment on patients who have suffered from arterial hypertension for a long time and whose range of pressure over a period of years was known, has shown, as a rule, little evidence of specific effect. The most striking results in many ways have been obtained in patients whose hypertension was apparently of brief duration and in whom anatomical alterations have not yet taken place. The evidence obtained from such a group, however, cannot be entirely convincing. Improvement in symptoms has been a very striking feature in many patients even where no fall in blood pressure was observed. The evidence at the present time that the liver extract was effective in certain cases of arterial hypertension was very suggestive but not conclusive.

The Treatment of the Peripheral Vascular Disturbances of the Extremities.—Dr. George E. Brown, of Rochester, Minn., said that there were two main types of vascular disturbances involving the extremities, those of a functional or vasomotor origin, and those of an organic origin. The vasomotor disturbances were of two types, depending upon whether there was overaction of the vasoconstrictor or the vasodilator mechanism. Raynaud's disease represented a disturbance in which the peripheral constrictor mechanism was overactive. The peripheral arteries, capillaries, and venules participated in the disturbance. Erythromelalgia represented an overactivity of the vasodilator mechanism. There were two main disturbances of an organic nature: 1, thromboangiitis obliterans or Buerger's disease, and 2, endarteritis obliterans of an arteriosclerotic nature. The treatment of the vasomotor disturbances has been uniformly unsatisfactory. A surgical procedure which would interfere with or block the vasomotor paths to the distal vessels has long been sought. This was accomplished in the feet by removal of the second, third, and fourth lumbar sympathetic ganglia, and stripping the common iliac arteries as carried out by Adson. Calorimetric studies have demonstrated marked increases in the blood volume flow in the feet and clinical cure has resulted persisting to date.

The treatment of the diseases of an organic nature have been likewise difficult. Amputation has been the usual surgical procedure in thromboangiitis obliterans or Buerger's disease in the presence of gangrene and excessive pain. Lumbar sympathetic ganglionectomy has relieved pain and produced an increase in the blood flow of the feet as shown by surface temperature studies and determinations of the rate of heat elimination. Intravenous injections of radium chloride have given pain relief in Buerger's disease in fifty per cent. of cases for short periods of time. Intravenous injections of typhoid vaccine to produce systemic fever have been the most successful medical measures for alleviation of pain and increasing circulation in Buerger's disease. Protective measures in

conjunction with other measures were essential, as Buerger's disease was eventually bilateral. Prevention of amputation was the goal sought for. Eighty per cent. of the patients with Buerger's disease had had erroneous diagnoses before coming to the clinic. Much valuable time had been wasted, with various orthopedic and other measures during the early stages of this disease.

On the Use and Abuse of Heliotherapy in Tuberculosis.—Dr. Samuel H. Watson, of Tucson, Ariz., said that direct sunlight was a powerful agency, but it was as powerful for harm as it was for good. There was increasing evidence that in the treatment of tuberculosis heliotherapy was often excessively and unwisely employed. Its proper use should be confined to certain definite types of the disease, and even in these types, it should be practised only with extreme caution.

Chronic Hereditary and Familial Hemolytic Jaundice With Splenomegaly and Hepatomegaly: Further Observations on Five Cases Under Study.—Dr. W. Forest Dutton, of Amarillo, Texas, said that the cases under study represented the occurrence of this condition in five generations and were of special interest owing to the comparatively rare but characteristic features. The disease differed from that described by Murchison, Minkowski and Chauffard as congenital or familial hemolytic jaundice, in the very decided functional activity of the liver and its relation to the reticuloendothelial system. During the periods of crises, the concomitants of ordinary obstructive jaundice, such as clay colored stools, choluria, mild pruritis and slight icterus were present. The blood picture was markedly characteristic, but at times exaggerated. This made the diagnosis comparatively easy. An intimate study of these cases appeared to implicate the extrahepatic bile passages and the reticuloendothelial system. In explanation of the pathogenesis of jaundice of this type, it was obvious that jaundice was due most frequently to impairment of the excreting function of the liver. That is to say, the condition was usually traceable to inflammatory or degenerative changes of the liver cells. Mechanical or other obstruction to the outflow of the bile caused the bile to back up in the liver cells. This action damaged the cells by inflammatory or degenerative process and facilitated the accumulation of preformed bile in the liver cells. In the production of crises, the neuromuscular reflex apparatus of the bile passages played an important role. A total of spasm of the region of the sphincter of Oddi with contractions of the gallbladder, which force the bile back to the columns of the liver cells, produced a toxic irritative process of defense reaction in the hemopoietic apparatus.

In one of the cases under study, splenectomy was followed by marked improvement; in another, cholecystectomy apparently cured the condition. The severer the affection, the shorter the interval between crises. This was governed, however, by the degree of the inflammation of the ducts and the involvement of the sphincter of Oddi. In the milder cases, the duodenal tube, introduced after the method of Meltzer-Lyon, was frequently a prompt palliative measure; the severe cases may necessitate the removal of the gallbladder or spleen. Nonsurgical procedure in three cases proved eminently satisfactory. The predisposing causes of the crises should be taken under consideration. Proper diet, regulated exercise, fresh air and sunlight, freedom from excitement and sudden changes of temperature, and prevention of infections are essential prophylactic measures. Iron, arsenic and nuclein were administered by mouth and hypodermically with only fair results. The best results were secured by the intravenous use of these drugs.

It was inferred from the studies made that the close cooperation of the internist and surgeon would prove the solution of the problem presented by this disease.

SECTION ON GASTROENTEROLOGY AND PROCTOLOGY

CHAIRMAN, DR. SIDNEY K. SIMON, OF NEW ORLEANS.
SECRETARY, DR. FRANK SMITHIES, OF CHICAGO.

Epigastric Hernia: Its Diagnostic Importance in Gastrointestinal Affections.—Dr. Julius Friedenwald and Dr. Theo. H. Morrison, of Baltimore, Md., on the basis of a series of sixty-five cases of epigastric hernia, presented the following study:

Epigastric hernia, a rupture appearing in the linea alba between the umbilicus and ensiform cartilage, is an affection of not infrequent occurrence. However, insufficient attention has been accorded its importance. This is largely due to the fact that, inasmuch as many of these hernias are reducible and disappear in the recumbent posture, the position in which patients affected with abdominal disorders are ordinarily examined, they are frequently overlooked. This form of hernia constitutes from eight hundredths to three per cent. of all hernias. It occurs mainly in adults. It is rarely noted before the eighteenth year, and in the largest proportion of instances it occurs between the twentieth and fiftieth. A few cases have been observed during early childhood, and Sir Ashley Cooper and Cumston report two instances each of congenital origin. The disease is most frequent in males and definitely more in the laboring classes, especially in those subjected to strain upon the abdominal muscles.

Etiology.—Epigastric hernia is ordinarily acquired though occasionally it occurs congenitally. The acquired forms are due to trauma or prolonged strain upon the abdominal muscles; however, even in the acquired forms a congenital defect in the abdominal wall may exist, and by strain the preperitoneal fat may be forced to protrude. Further etiological factors have been noted in the form of weakness of the abdominal muscles caused by prolonged illness, emaciation, excessive vomiting, or coughing, or to direct trauma as from blows upon the abdomen.

Symptoms.—The symptoms vary greatly in different individuals and their severity is in no way proportionate to the size of the hernias. Frequently the patient is unaware of the presence of the hernia until it is accidentally discovered, and many years may elapse before symptoms are manifested. In others the symptoms are so slight, that the patient himself attaches but slight importance to them. Often tenderness on pressure over the region of the hernia is the first and only sign noted. This sign is of paramount

importance in the diagnosis of this condition, and occurs whether the hernia is reducible or not. The finding of this tender area along the linea alba is of the greatest aid in the diagnosis of this condition. In about half the cases the symptoms become aggravated, and may take the form of intense colicky paroxysmal pain appearing in the epigastrium especially on exertion or after intense coughing. The pain is most pronounced at the site of the hernia and is increased on pressure over this area. It may radiate to the back, chest, lower abdomen or legs and is often increased upon bending and when in the upright posture, and is relieved by reclining on the back. Other symptoms noted are loss of appetite and weight, nausea, vomiting, eructations, flatulency, distention, constipation and, occasionally diarrhea. Hematemesis has been rarely noted, and is usually associated with attacks of profuse vomiting. The symptoms may occur often in attacks continuing on for hours and days, and may recur at irregular intervals.

The symptoms may resemble those observed in ulcer of the stomach and duodenum, cholelithiasis, gastritis, ulcerative colitis, carcinoma, pyloric obstruction and chronic appendicitis.

On inspection of the abdomen a visible tumor may at times be observed in epigastric hernia along the linea alba between the ensiform and umbilicus; noted especially when the patient is in the erect posture.

On palpation the mass presents the sensation of a bit of fat and on coughing as if fluid were forced against the hand (*Spritzgefühl Lenhoff*). This sensation does not occur with tumors. An "electric bell reaction" has been described by Hall in the form of instantaneous belching by a touch on the hernia. This sign was noted in but a few of our cases.

In from twenty to twenty-five per cent. of the cases hyperchlorhydria is noted in the gastric contents together with a lowered motility and not infrequently visceroptosis with atony of the stomach.

Differential diagnosis.—Ordinarily but slight difficulty is encountered in the diagnosis of epigastric hernia, providing a painstaking physical examination is made of the abdomen. However, it is of importance to note that this form of hernia should not be confused with the ordinary umbilical hernia or visceral protrusions associated with diastasis of the recti. Attention has already been directed to the fact that the symptoms frequently resemble those of ulcer of the stomach and duodenum, cholelithiasis, gastritis, cancer and pyloric obstruction with which conditions it has been not infrequently confounded. While both epigastric hernia and ulcer have been observed in the same individual, many cases without question are confused with ulcer. In all instances in which atypical ulcer signs are present, or where malignancy is suspected, a thorough examination should be made so as to determine the presence of epigastric hernia. A careful x ray investigation with examination of the stools for blood will frequently point to the correct diagnosis. One cannot, however, lose sight of the fact of the possibility of the development of carcinoma of the stomach in a patient with epigastric hernia.

Treatment.—Certain cases are symptomatically relieved under medical treatment by means of applications of abdominal supports, binders or trusses providing the hernia is reducible. Such measures are, however, harmful when the hernia is irreducible and may actually aggravate the condition. The radical operation is simple and should be urged upon all patients unless some definite contraindication exists. Relapses following operation are infrequent.

Duodenal Stagnation.—Dr. Ernest Clyde Fishbaugh, of Los Angeles, Cal., reviewed the literature, and discussed duodenal stagnation as observed with no organic pathology. He said the symptomatology showed epigastric distress, anorexia, nausea, loss of weight, exhaustion and weakness. The physical findings were undernutrition and anemia. The laboratory diagnosis was based on bile in fasting stomach and at other times, and x ray evidence of a dilated duodenum. The treatment was rest in bed, corrected undernutrition and anemia, and abdominal support.

In duodenal stagnation as observed with organic pathology, the author said that when due to adhesions or scars, there was a history of previous operations, injury or ulcer; when due to carcinoma, there was a carcinoma within the duodenum or outside; tumors of the pancreas, gallbladder or ducts, stomach, kidney, retroperitoneal glands involving the duodenum. The symptomatology was the same as in duodenal stagnation with no organic pathology, with the addition of the carcinoma symptoms; and the physical findings were rarely a palpable mass; otherwise the same. The laboratory diagnosis was based on regurgitate bile in stomach, x ray evidence of duodenal stagnation, and stool findings. The treatment in these cases was operative.

The author's conclusions were that, a, duodenal stagnation was a more frequent condition than the medical literature would indicate; b, duodenal stagnation without organic cause could be successfully treated medically; and c, duodenal stagnation with organic cause should be treated surgically.

SECTION ON PATHOLOGY AND PHYSIOLOGY

CHAIRMAN, DR. HARRY J. CORPER, OF DENVER.
SECRETARY, DR. JOSIAH J. MOORE, OF CHICAGO.

On Conduction and Contraction of Cardiac Musculature in Water Rigor.—Dr. Clyde Brooks, of Tuscaloosa, Alabama, said that in a former paper, (*American Journal of Physiology,* 1906, vol. XVII, p. 218), he showed that skeletal muscle in water rigor loses its conductivity and its contractility at practically the same time. This is contrary to the results obtained by Biedermann who found that the frog's sartorius was able to conduct while in water rigor. Biedermann's results were used by Engelmann in his argument that the frog's auricle, when in water rigor, apparently conducted the contraction impulse without itself contracting. But according to the results obtained by Brooks, in his first article on water rigor, the muscle in Biedermann's experiment was not in complete rigor. Only the outer portion was in rigor. The inner core was normal. The inner, normal tissue contracted and conducted the impulse in a normal way. The present article carries out the same line of work on cardiac musculature. It shows that the frog's auricle does not conduct nor contract when it is in complete water rigor; but it conducts the impulse when the outer portion of the auricle is in

igor, which makes the auricle stiff and unable to contract (shorten). However, the inner portion contracts without shortening, and thus carries the impulse to the ventricle. The whole effect of these two articles is to support the neurogenic theory for the origin and conduction of the heart beat.

A Simple Practical Method of Estimating Blood Volume for Clinical Purposes.—Dr. W. N. Duke, of Kansas City, Mo., referred to the time honored custom of physicians diagnosing anemia or plethora by observing a patient's color, and said that his method of diagnosis was hopelessly incorrect, as in individuals having apparently normal quantities of blood, some had red faces, red lips and rosy ears, while others had pale faces, pale lips and pale ears. Furthermore, there was no standard of color to go by, and the patient's color was compared rather with the physician's idea of what normal color was. The face was an organ of expression, subjected to marked variation in color under the influence of many factors, such as emotion, change in temperature and exercise. The conjunctivæ, a time honored location for the estimation of color, was also subjected to variation under conditions other than those due to change in quantity of blood. When anemia was marked, pallor of conjunctivæ was observed with definiteness; when blood quantity was markedly increased, a tinging of the scleræ with pink became evident, which could not be observed with accuracy or definiteness when the change was small. This crude method of diagnosis has been properly supplanted to a large extent by laboratory examinations. With many physicians laboratory examinations have completely supplanted it, and they often assumed that a person was normal so far as blood quantity was concerned if the red count, hemoglobin per cent. and blood smear were normal. This was incorrect, for in many individuals who had normal red counts the blood volume was increased or reduced. If the red count and hemoglobin per cent. are known and if the volume of circulating blood were known, the total volume of circulating hemoglobin could be calculated. This was the all important fact to know in order to decide if the patient was anemic, plethoric or normal, but such a method of determining blood quantity, or rather mass quantity of hemoglobin, was too elaborate for general use.

The author described a method of estimating mass quantity of hemoglobin which he found to be remarkably practical and accurate enough for clinical purposes, that of comparing the color of the patient's palm with that of a normal individual. He said that the skin surface of the palm of the hand varied little unless the blood quantity was increased or decreased; it was not influenced by heat or cold, exercise, emotional disturbances or other factors as other skin surfaces because the palm of the hand was not an organ of expression, nor did it perform any important function in the regulation of body temperature as other skin surfaces do. Its color was rarely influenced by common conditions and common diseases except anemia or plethora, and for this reason was an ideal locality for the diagnosis of anemia or plethora. The author discussed the technic in detail, and said that when comparison was made patient and physician should stand or sit comfortably. The hand of each should be semiflexed and should be held at about the level of the apex of the heart. It was essential that the distance between the hand and the base of the heart be identical in both physician and patient and that in neither should the skin of the palm be stretched. It was assumed, of course, that the physician's hand was normal in color, thus a standard to go by. If the patient was slightly anemic his palm would be paler than the physician's, though the finger tips might appear the same. If the patient was anemic to such an extent that quantitative changes had occurred in the blood, if the red count or hemoglobin per cent. was slightly reduced, the difference in color between the patient's hand and the physician's would be so striking that it could not possibly be overlooked; the patient's finger tips and palms would both look white by comparison.

The author asserted that comparison of the palm of the patient's hand with that of a normal individual during and after blood transfusion and during and after venous section was a most reliable guide in deciding whether or not an adequate amount of blood had been introduced or withdrawn.

Evidences of Diseases as Shown in Fossil and Prehistoric Remains; Paleopathology.—Dr. F. B. Young and Dr. A. L. Cooper, of Scottsbluff, Nebraska, presented a short review of geological and paleological history, with an explanation of conditions governing the deposition of fossil material. Their material was almost wholly from the Cenozoic Era or Age of Mammals, and showed conditions of periostitis; osteitis, osteoma; osteomyelitis; arthritides, of both productive and destructive types; fractures, simple, compound, with excessive callus, and with infection; diseased teeth, with impaction of permanent and deciduous teeth, caries, and malformation; pyorrhea; necrosis of mandible, and other diseases, all of which were commented upon. A discussion of the persistence of certain types of bone lesions from the earliest of vertebrate life was presented. These persistent types were those mentioned above, and vertebral diseases of both the arthritis deformans type and the destructive or tuberculous type. All diseases so far identified were inflammatory in origin but neoplasms might be identified later by more careful histological examination. The authors discussed the origin of disease processes as suggested by the great antiquity of diseases.

Aspergillosis of the Lungs and Its Association With Tuberculosis.—Dr. Mary E. Lapham, of Highlands, N. C., said that her paper attempted 1, to describe from autopsy reports the pathological changes wrought in the lungs by *aspergillus fumigatus*; 2, to suggest the probability that aspergillosis of the lungs may predispose to tuberculosis; 3, that when both infections coexist, aspergillosis may complicate or inhibit recovery; 4, that aspergillosis is a primary disease which may result in pleurisies (acute and chronic), pneumonia, asthma, chronic bronchitis and the clinical picture of tuberculosis from which it can only be distinguished by cultures and inoculations; 5, that the stigma of tuberculosis should never be fastened upon a closed case without the diagnosis being confirmed by inoculations; 6, that every open case of tuberculosis should be tested for the complicating presence of aspergillosis; and 7, that the same problems might apply to cows.

SECTION ON OPHTHALMOLOGY

CHAIRMAN, DR. ARNOLD KNAPP, OF NEW YORK.
SECRETARY, DR. WILLIAM C. FENNOFF, OF DENVER.

Refractive Changes.—Dr. E. C. Ellett, of Memphis, Tenn., said that his paper consisted of a discussion of the changes that occur under the following circumstances: a, axial changes, increase of myopia, decrease of H, rarely the reverse; b, changes of curvature, usually of the cornea, temporary or permanent, corneal astigmatism, changes in lens curve, "second sight" by swelling in beginning cataract, same effect from increase of index of refraction of lens; c, change of index of refraction of media, lens aqueous and possibly vitreous from diabetes, quinine, inflammatory products, etc., iritis; d, muscular action; and e, unclassified or combination types.

Röntgenological Investigation on Four Hundred Optic Canals in the Living: Clinical and Anatomical Data.—Dr. Harry A. Goalwin, of New York, presented an analysis of four hundred canals investigated in two hundred patients for twenty-two different causes. Twenty types of pathology were found in forty-one per cent. of the cases; pathology found röntgenologically elsewhere in the skull in thirty-six per cent. Skull deformity with optic nerve symptoms occurred as frequently as optic nerve tumor. Among the changes observed were: fracture, hyperostoses, exostoses, periostitis, constriction, enlargement, destruction of roof and outer wall, erosion of all walls, foreign body, aneurysm of ophthalmic artery, osteomata, calcification of atrophic nerve, optic nerve tumor. The optic canal axis makes an average angle of thirty-eight to thirty-nine degrees with the horizontal as well as the vertical plane of the skull, irrespective of sex or racial stock; and has an average size of cross section of 4.1 by 4.5 mm., irrespective of age, sex or stock. No optic canal under 2.8 mm. diameter can contain a normal optic nerve.

A Clinical and Pathological Study of the Anterior Lens Capsule.—Dr. Arthur J. Bedell, of Albany, N. Y., said that his paper was a review of the anatomy and pathology of the lens capsule and was illustrated by photomicrographs and hand drawings. The congenital changes, such as pupillary membrane remnants and ganglion cell shaped areas of pigmentation, were discussed. He said it was possible to differentiate between regular and irregular folds of the capsule and also between those which were the result of spontaneous lens shrinking or traumatic lens absorption. In the latter the wrinkles were narrow with marked iridescence, while in the former the ribbons were decidedly broader. It was asserted that rupture of the capsule might be either partial or complete. A description of each type was given. The normal zonule of Zinn and its pathological variations were described. The numerous types of iris adhesions with exudate and vascularization were illustrated by case histories and pictures. Two unusually interesting cases were detailed, one a diabetic iritis injudiciously treated with insulin, the other a chronic iritis in which, following an iridectomy, the zonular fibres were slowly absorbed. The lens was finally dislocated in the vitreous from which it was removed with full restoration of vision. Another case illustrated the need of dilating the pupil to disclose the full extent of capsular changes. This was a minute laceration at the margin of the iris which, after the use of atropine, was found to be part of the torn sheet.

The author further stated that the examination of the anterior capsule could be made in life and the findings corroborated in the laboratory. In the ordinary sized pupil, "stars," exudate, pigment, various forms of adhesions, wrinkles and ruptures were seen; whereas when the pupil was dilated, a larger field was exposed, adhesions were stretched and a more complete examination was possible. The peripheral zone was the one of great interest because in it the zonular fibres were traced to their lens attachment. The congenital changes were recognized and the prognosis regarding them was more accurate as a result of slit-lamp examination. Finally, the anterior capsule must be carefully studied in the living eye if a complete understanding of it is to be made possible.

Color Blindness in Industry.—Dr. Archibald E. Chase, of Texarkana, Ark., said that examination for color blindness in applicants for hazardous occupations requiring color perception should be carefully performed. Some facts of the physics, physiology, pathology, incidence and classifications of color blindness were given. The important factor was the ability of the color blind to distinguish colors by intensity.

A review and classification of over one hundred tests for color blindness were given and a method suggested for recording cases of color blindness.

Rejection of applicants was discussed, and conclusions were drawn as follows:

1. It is clear to me that one who has not made a study of color sense and its pathology is not in a position to test applicants for occupations requiring color perception.

2. I believe that the stations at which such tests are made should be reduced to the fewest practical number, and the work at each should be periodically checked.

3. The usual test by worsteds alone eliminates only fifty per cent. of the dangerously color blind, and should be immediately discarded as the sole test of an applicant for train, yard and engine service on railways.

4. The Eldridge-Green type of lantern is the only lantern with sufficiently broad and accurate application to warrant the expense of purchase by industrial concerns. It should be used in conjunction with a simultaneous comparison test of the stilling plate type.

5. For day signals by reflected light, as in semaphore arms, switch targets, station boards, and flags, the tests above are sufficient. The saturation and intensity as well as wave length analysis of such signals vary greatly on different railroads and at different times. Such signals should have contrasting colors to prevent confusion with the background.

6. Field tests as ordinarily conducted by railroad officials are of little value. They are supposed to be made under working conditions. As a matter of fact they are frequently made under ideal conditions, with no conception in the mind of the official of what the

ests are intended to develop, of the effect of various atural conditions, and only rarely with any knowlge of the pathology of vision. If field tests are o be made at all, they should be conducted by experts, ith specially constructed apparatus using the standrd roundels and flags under all natural conditions of team, rain, fog and smoke, daylight, night, dusk or awn, at proper distances, with controls, by a method lanned in advance to cover all of the 288 possibilies.

7. For train, yard and engine service a man should ee all the spectrum with the possible exception of range, should not have a central color scotoma, hould not be markedly weak in any color, or be color gnorant or aphasic. Shortening of the red end of the pectrum should be positively eliminated.

In conclusion, let me leave this thought with you. ndustry looks to the ophthalmologist to examine aplicants and employees for color defects in vision ithout any question as to the quality of method or nowledge. How many are in a position to fulfill his trust and what percentage of you make a sufficiently accurate determination in every case of defective color sense to be able by concerted action to eply in time to the many unanswered problems in his field?

SECTION ON LARYNGOLOGY, OTOLOGY, AND RHINOLOGY

CHAIRMAN, DR. SAMUEL IGLAUER, OF CINCINNATI.
SECRETARY, DR. WILLIAM V. MULLIN, OF CLEVELAND.

Indication for Tonsillectomy in Children Based on End Results.—Dr. Alfred D. Kaiser, of Rochester, N. Y., said that the end results for tonsil nd adenoid operation were generally based on the mpressions one gained. If a careful investigation was made the favorable progress of a child was ttributed to the operation and no mention was made f the child who does equally well but in whom the onsils had not been removed. When one compared hese children in groups the striking results one anicipated were not so obvious. So long as tonsillecomy was restricted to extreme cases uniformly good esults would follow, but when one entered the field f prophylactic tonsillectomy less striking results were obtained and it became more difficult to contruct definite indications for the operation. If by areful control study it could be shown that the child who was subjected to this operation, even though here was no outstanding indication, was a little beer off ultimately than his unoperated colleague a ustification for the operation existed. Such an atempt had been made in this study. Based on an nalysis of the complaints of 1,200 children with the esults found three years later and compared to 1,200 hildren with similar complaints but in whom operaion was denied but also examined three years later, he following conclusions can be made bearing on he indications for tonsillectomy and adenectomy: , mouth breathing was a definite indication for tonsil nd adenoid removal; 2, frequent attacks of sore hroat and tonsillitis offered a definite cause for reoval of tonsils; 3, frequent head colds, relieved in eventy-five per cent. of the cases offered a definite ndication for tonsil and adenoid removal; 4, persistent enlargement of the cervical glands where no other cause was found was a just cause for tonsil removal; 5, malnutrition when other causes have been eliminated will be improved somewhat and therefore may be considered an indication; 6, chronic and recurrent discharging ears was an indication for the operation; 7, unexplained fevers, in the absence of other indications, may be a great cause for tonsillectomy but was no guarantee that they will not recur unless the fever came from an obscure infection; 8, for the prevention of respiratory infections such as laryngitis, bronchitis and pneumonia no positive indication existed as the incidence of infections was not influenced favorably or unfavorably by operation; 9, the prevention of diphtheria and scarlet fever may be considered an indication as the incidence of these diseases was slightly less in the operated group and where it did occur the sequelæ were less serious where the tonsils had been removed; 10, the presence of positive or unsuspected evidence of the rheumatic syndrome manifestations, rheumatism, chorea and heart disease was a definite indication for tonsillectomy in view of the lessened incidence of heart disease in the operated group.

Vertigo: Its Incidence in Endocrine Disorders.—Dr. Dana W. Drury, of Boston, said that in the study of vertigo, the most common difficulty was to ascertain definitely to what condition the patient applied the term vertigo, giddiness or dizziness. This was probably due to the fact that vertigo consisted of subjective symptoms which in each case required psychological analysis. Such an analysis was often impossible, both because of the transient confusion and inattention of the patient to his sensations during an attack, and also of the inadequacy of the language of the ordinary untrained observer to describe properly such abnormal and pathological sensations. It was also realized that vertigo might be a physiological as well as a pathological condition of the patient.

The paper offered the results of an investigation into the relative incidence of vertigo in disorders of the endocrine system. The report was based on the analysis of 1100 consecutive cases, all presenting stigmata of endocrine disease, received at the Evans Memorial for diagnostic study. The methods of analysis have been described elsewhere in detail and in brief may be said to comprise the collation of results from very thorough and comprehensive clinical and laboratory observations.

Of this series 377 or thirty-four per cent. presented a primary pathology which was nonendocrine in origin. Of this number seventy-six showed vertigo. The allocation of these cases to certain broad diagnostic groups was given in a tabular summary.

The most striking feature of the study was the relatively uniform incidence of vertigo in the major endocrine groups and four well characterized nonendocrine conditions. Lesions of the central nervous system showed nearly sixty per cent. increase in frequency, while in the other nonendocrine conditions the frequency of appearance was of the order of one in ten. The adrenal and pluriglandular cases were too few in number to make authoritative the absolute magnitudes observed. It is certain from this analysis that vertigo cannot be regarded as a sign presenting significance in the diagnosis of endocrine disease.

Abstracts from Current Literature

NEUROPSYCHIATRY

Surgical Treatment of Habitual Criminals, Imbeciles, Perverts, Paupers, Morons, Epileptics, and Degenerates.—A. J. Ochsner (*Annals of Surgery,* September, 1925) recommends a form of treatment for these degenerate classes by which society may protect itself against their progeny. It does not injure the individuals treated, causes no pain, produces no deformity, incurs no danger to life, interferes in no way with the health and happiness of those treated, and contains no element of punishment. It consists in the ligation and section of the vas deferens as follows:

1. Disinfection of the skin area; 2, infiltration of the skin and the tissues about the vas deferens with one per cent. solution of novocaine, or its equivalent; 3, an incision two cm. long; 4, the bringing forward of the vas; 5, double ligation one cm. apart with silk or catgut; 6, section of the vas above the point of ligation; 7, closure of the wound with one or two catgut sutures and dressing of the wound.

Postencephalitic Psychoses.—P. K. McCowan (*Lancet,* February 7, 1925) states that certifiable insanity is extremely rare as a sequel to encephalitis lethargica. It is highly probable that the virus of encephalitis lethargica has the power of remaining in the central nervous system in a potent form long after the subsidence of the acute symptoms. Many cases of insanity following encephalitis lethargica may not be true sequelæ, the encephalitis merely acting as a precipitating psychic cause. The possibility of suicide following encephalitis lethargica must not be lost sight of. Systematized delusions and dementia are sometimes found in postencephalitic psychoses. Psychotic symptoms during the acute phase of the disease are toxic in origin and of much better prognosis than postencephalitic psychoses. In the very rare event of a recovery in the latter it is practically certain that the case would not be one of a true sequela but of the secondary psychic type.

Condition of Accessory Sinuses in Encephalitis Lethargica.—A. Lowndes Yates (*Journal of Laryngology and Otology,* October, 1925) is inclined to think that in encephalitis lethargica, a condition of inflammation such as has led to a lack of function of the mucous membrane, namely, a ciliary paralysis and paralysis of mucous secretion, occurs, and there is a greatly heightened power of absorption of the mucous membrane.

It follows therefore that, if this hypothesis is correct, only those members of the community who suffer from this type of sinusitis in this region of the nose are potential subjects of encephalitis. It is necessary, however, for the transmission of the disease from one individual to another, that the air borne and filter passing virus of encephalitis lethargica should fall on soil previously prepared by inflammation which has produced an alteration in the normal mucous membrane, causing sinusitis or rhinitis, with total or partial paralysis of cilia and mucous secretion. The changes in the mucosa are produced either as a result of chronic rhinitis, or from a single heavy infection of the nasal mucous membrane, of the type known colloquially as influenza.

Epidemic Encephalitis.—L. Bériel (*Bulletins et mémoires de la Société médicale des hôpitaux de Paris,* March 11, 1926) describes a form of encephalitis of which hundreds of cases have recently been observed in southeastern France. This form is clinically like multiple neuritis, and corresponds to the group termed by the author and Devic the "peripheral forms" of encephalitis. There are various indications pointing to an involvement of the whole spinal neuron in these cases. There is progressive, then regressive, flaccid paralysis, with a tendency to loss of the tendon reflexes and to wide diffusion, the cranial nerves being sometimes involved. Recovery follows nearly always, though there are some exceptional deaths from sudden bulbar involvement. A related group of cases is one in which the flaccid paralysis and loss of reflexes so particularly affects the trunk and the proximal portions of the limbs that the condition can be distinguished from the acquired myopathies only by consideration of the earlier course of the disturbance. Excised bits of tissue in such cases have shown actual muscular lesions of inflammatory type. Dozens of these cases have been observed, with uniform recovery. Sometimes there are muscular pains. In a third group of cases, with or without distinct encephalitic symptoms, the picture is at first that of multiple neuritis, but this passes slowly or through repeated relapses to the production of spinal manifestations. The reflexes continue lost, but the flaccid paralysis is replaced by a tendency to contracture, with Babinski's sign, urinary disturbances and bedsores, and sometimes exaggerated postural reflexes. The disturbance may then become stationary, leaving a chronic syndrome that recalls certain cases of disseminated sclerosis, or may continue to progress, with appearance of anesthesias of the spinal type, ascending phenomena and death. In addition to these groups, there have been appearing in recent years very many cases of the meningeal type, hard to differentiate from tuberculous meningitis and certain syphilitic cases. The simplest general classification of the protean clinical forms of encephalitis is that into the central, mesencephalic or bulbospinal forms; the meningeal forms; the peripheral forms with possible myopathic aspects, and the forms leading to spinal scleroses. All these forms, in different localities or epidemics, may be modified, present symptoms of the encephalitic series, or become merged. Among the important superimposed symptoms appearing as encephalitic indications are edema, sweating, and sympathetic and vasomotor symptoms in general. Muscular atrophy may occur, but only exceptionally is it permanent, in contrast to that of poliomyelitis. A clinically important feature of the polyneuritic and myopathic forms is the usually favorable prognosis; this applies even where the patient has lost all power of motion in the limbs or trunk.

The Rôle of the Nervous System in Metabolism—Influence of the Endocrine Glands.—A. Oswald (*Revue Française d'Endocrinologie,* March, 1925) calls attention to the fact that adrenalin, the pituitary hormone, and the hormone of thyroid gland all act upon metabolism in special ways and all have an intimate connection with the nervous system. His inference is that their effect upon metabolism is not on the cells directly, but accomplished through nervous channels. He cites cases to show that individuals in whom the administration of iodine excites the nervous phenomena of hyperthyroidism are all persons of great nervous lability and lose flesh rapidly under the medication. The recognition of this relation, he believes, greatly simplifies our conception of the office and effect of the endocrine organs. Their secretory products are agents which stimulate the nervous system, and upon this action in final resort depends the normal conduct of the phenomena of metabolism. The secondary character of hormones is rightly comprehensible only when the activity of the endocrine organs is fully understood to be under the control of the nervous system.

The Conditioned Reflexes and Children's Neuroses.—(*American Journal of Diseases of Children,* December, 1925) N. I. Krasnogorski, of Leningrad, Russia, from an investigation of conditioned reflexes in both normal and defective children, considers that "the normal highest nervous activity, the whole behavior of the child, is founded on the highly flexible balancing between irritation and inhibition." He finds also that "the keeping of the balance in children and in animals sometimes requires great energy. Every limitation of irritation by inhibition, every formation of the antagonistic conditioned reflexes, produces some symptoms of general excitement or inhibition. The intensity of these symptoms depends on the power of the reflexes which are being inhibited. The more intense the stimulation is, the more difficult it is for the organism to limit and inhibit it. Sometimes the mobilization of all resources of the nervous system of the child are needed in order to suppress a reflex of great power. In some children we observed restlessness, active defensive reaction, crying, while in others we observed a general inhibition with the complete disappearance of conditioned reflexes and even with the development of a deep sleep. The disturbances of the balance in pathologic children have, as a rule, a more lasting and profound character than in normal children. The intensive conflicts between irritation and inhibition form a favorable soil for the origin of different neuroses in childhood."

Incipient General Paralysis.—Henry A. Bunker (*American Journal of the Medical Sciences,* March, 1926) presents this summary:

1. If certain nervous or mental symptoms are consistent with incipient general paralysis, as certain ambiguous physical symptoms may be consistent with early tabes, then the presence of such symptoms in a patient, if they are not otherwise clearly to be accounted for, calls at least for examination of the pupils and of the knee and ankle jerks and for Wassermann test, and raises the question, even when the evidence from these two sources is negative, of the necessity for lumbar puncture.

2. A study of the earliest symptoms which may occur in patients who later develop outspoken general paralysis, such as has been carried out in seventy-four male patients and here reported, may throw some light upon the symptomatic indications for the dignostic procedures just mentioned.

3. In this study it was found that irritability holds first rank as an early symptom, since it occurred as the earliest abnormality, or one of the earliest, in forty-two, or fifty-seven per cent. of the seventy-four cases.

4. The character change whereby an individual is reduced in activity and spontaneity, loses some of his interests, tends to withdraw into himself, and is often described as having become "quiet," is likewise a common early symptom, for it occurred in twenty-eight, or thirty-eight per cent, of these cases.

5. Loss of weight as an early manifestation ranks third numerically. It occurred—and very often early—in twenty-two, or thirty per cent, of this series.

6. An increased tendency to sleep, somewhat more suggestive in itself than any of the foregoing symptoms, was an early manifestation in fifteen cases, or twenty per cent.

7. Speech defect, memory defect, and judgment defect have considerable diagnostic value in themselves, but they were found in this series among the earliest symptoms in only eleven cases, fifteen cases, and seven cases, respectively.

8. Visual impairment, digestive disturbance, insomnia, fatigability, headaches, tremor, and rheumatoid pains were present as the earliest manifestations in a few cases; neurosyphilis must sometimes be considered in the differential diagnosis of these very undistinctive symptoms.

Localization of Brain Tumors by Ventriculography.—W. Pierson (*Journal of Cancer,* October, 1925) states that an accurate picture of the ventricular system of the brain may be obtained roentgenographically by the withdrawal of cerebrospinal fluid from the ventricles and the substitution of air. By examining first one side and then the other it is possible to obtain separate roentgenograms of each lateral ventricle. Following the completion of each lateral view, the head is carefully turned and the occiput placed down. This position will give the size, shape and position of the anterior horns of both lateral ventricles and show a cross sectional view of the third ventricle. Finally, a posteroanterior examination is made, which gives the desired information regarding the body and the posterior and descending horns of the lateral ventricles. The findings must absolutely indicate the position of the tumor. Moreover, the presence of suspected tumors can be excluded in fifteen per cent. of the cases on the basis of negative findings following the complete examination.

Most tumors are localized by the effects produced on the two lateral ventricles, though the third and fourth ventricles play an important part. A tumor of any size situated in either cerebral hemisphere will be shown by filling defects and a displacement of the corresponding ventricle. The opposite ventricle may also be dislocated and its size modified. The tumor by its size or position may cause obstruction of one or more of the ventricles, as shown by a dilatation of the ventricles and by inability of the air to pass beyond the point of obstruction. The location of the point of obstruction will immediately locate the tumor. A cerebral tumor can be differentiated from a cerebellar tumor, because the internal hydrocephalus accompanying the latter is demonstrated by a symmetrical enlargement of the lateral ventricles.

The procedure of Dandy consists in making two small openings in the posterior portion of the skull. A needle is inserted in the posterior horn, and the cerebrospinal fluid is aspirated in small quantities to prevent a negative pressure. An equal amount of air is substituted for the fluid withdrawn. If a ventricle is so reduced that it is impossible to withdraw sufficient fluid to make the injection of air a safe procedure, the opposite ventricle should be punctured and air injected. The air should be withdrawn, especially if a large amount has been used, as soon as the x ray examination is completed.

The procedure is dangerous and complicated, but in competent hands it should not be nearly so dangerous as an exploratory craniotomy, and it frequently yields more information than the latter operation.

Wagner-Jauregg Treatment of Dementia Paralytica.—S. Grossman (*Lancet,* July 4, 1925) finds that the treatment of general paralysis with benign tertian malaria is justified; the technic is simple; the fever can be easily and quickly controlled by quinine. In the author's experience no malaria relapses have occurred. The more recent the case, the better the prognosis; but even late cases improved physically. The remissions are more marked than in the untreated cases. An attack of malaria seems to produce immunity to artificial inoculation. Arsenical medication used in any chemical combination only has failed in the treatment of general paralysis of the insane. The Wassermann reaction in the blood and cerebrospinal fluid, the Ross Jones and Weichbrodt reactions in the latter, remained unchanged. Neither are the cell contents of the cerebrospinal fluid influenced by the production of malaria. Even in cases of complete remission some physical signs of general paralysis of the insane remain, e. g., Argyll Robertson pupil; greasy complexion; and exaggerated reflexes.

Pharmacological and Therapeutic Effect of Ergotamin on the Sympathetic Nerve.—E. Rothlin (*Klinische Wochenschrift,* July 23, 1925) has shown that ergotamin—the alkaloid of ergot—in addition to the specific effect of ergot in obstetrical and gynecological practice, also possesses the property of paralyzing the peripheral endings of the sympathetic nerve in a selective manner. This specific paralyzing effect of ergotamin affects not only the stimulating end fibers of the sympathetic nerve, similar to that of ergotoxin, but also the inhibitory end fibres.

The pharmacological antagonism between pilocarpin and atropin exerted upon the parasympathetic nervous system is analogous to the antagonism between adrenalin and ergotamin upon the sympathetic nervous system. These pharmacological results, as well as the clinical experiences acquired up to date, speak in favor of the assumption that ergotamin should be assigned a great significance from a differential diagnostic and therapeutic viewpoint in sympathicotonic disease pictures.

Hydrocephalus.—McKim Marriott (*Medical Clinics of North America,* July, 1925) states that the first step in the treatment of hydrocephalus is to determine whether or not the hydrocephalus is the result of an active meningitis or if it is due to obstruction between the ventricles and subarachnoid spaces. Information regarding the first point can be obtained from an examination of the cerebrospinal fluid. The fluid obtained by lumbar puncture may be clear, whereas that obtained from the ventricles may contain an excess of cells or may even be definitely purulent. Both ventricular and lumbar puncture should usually be done. This is easily accomplished in the case of infants. Information as to communication between the ventricles and the subarachnoid spaces is obtained by observing whether or not there is a free flow of fluid on lumbar puncture, and if the fluids in the ventricles and in the subarachnoid spaces are under the same degree of pressure; further, whether pressure on the fontanelle causes a distinct increase in the flow of fluid from the lumbar puncture needle.

In the case of active meningitis due to the meningococcus appropriate serum treatment should be instituted, and it is well to note in this connection that in the case of infants with meningococcus meningitis it is advantageous to administer serum into the ventricles as well as into the spinal subarachnoid space. In syphilitic meningitis appropriate antisyphilitic treatment should be instituted. In the so-called acute hydrocephalus of tuberculous meningitis treatment is at best palliative and should consist in frequent lumbar punctures.

When hydrocephalus is of the communicating type, i. e., when there is free communication between the ventricles and the subarachnoid, diuretin should be administered, and usually this treatment leads to good results. When the hydrocephalus is of the noncommunicative type surgical procedures are indicated.

Cerebral Palsies of Early Life.—B. Sachs (*American Journal of the Medical Sciences,* March, 1926) maintains that in dealing with the cerebral palsies of children the exact form of paralysis is the unimportant factor. It is much more important to determine, whatever the form may be, whether the palsies are due to a morbid process that had its beginnings in the prenatal period, or at the very time of birth, or whether they were acquired later in life as the expression of vascular accident, or as the result of an infectious encephalitis.

The Plantar Lines in Mental Defectives.—Examination of the feet of 618 mentally defective children showed, according to Thomas Brushfield (*British Journal of Children's Diseases,* December, 1925) that 207 children had feet with three plantar lines, 102 had two plantar lines, 199 possessed one (oblique) plantar, while 110 had no plantar lines.

Psychical Disturbances in the Diseases of the Glands of Internal Secretion.—Study of a number of patients with palpable gland disease, such as exophthalmic goitre, myxedema, and diabetes, in the Boston hospitals inclines C. M. Campbell (*Endocrinology,* May-June, 1925) to believe the psychic features in these cases are due to constitutional factors and other causes, for the most part, rather than to the glandular lesion.

MALIGNANCY

Cancer Prophylaxis.—W. W. Chipman (*Canadian Medical Association Journal,* May, 1925) says that much can be done in the way of prophylaxis of cancer of the uterus and presents the following as good prophylactic rules:

1. If in any case of labour, the delivery has been affected by forceps, or by a breech extraction; if the child has been unusually large, or the labor precipitate; make an immediate examination of the cervix. If a tear be found deeper than half an inch, coapt the raw surfaces of this tear by interrupted catgut sutures.

2. In any obstetrical case, make invariably a "discharge examination." If any cervical lesion be found, treat it, or if repair be necessary, execute this at the end of lactation.

3. If at any time in the woman's menstrual life, the menstrual habit be depraved, in the way of a menorrhagia, a metrorhaggia, or a leucorrhea, make a thorough examination. It may be necessary to explore, or even to curette the uterus. Identify the lesion by the naked eye or microscope, and treat it as it deserves.

4. Uterine bleeding, however slight, or a conspicuous leucorrhea, occurring after the menopause, are danger signals. In such a case, if free bleeding follow the passage of a uterine sound, or the curettings be abundant, perform an immediate hysterectomy.

5. Remove by hysterectomy all submucous, or intramural fibroids.

A New Outlook on Cancer: Irritation and Infection.—James Young (*British Medical Journal,* January 10, 1925) states that there are two completely independent factors underlying the change of a normal cell into a cancer cell. The first is an antecedent cell susceptibility; the other is an immediate cancerogenic factor. Analysis shows the antecedent cell susceptibility to be the capacity for continued proliferation in the body, and when possessed naturally by the cells ("embryonic"), allows a development of cancer when the immediate cancerogenic factor is added. In the case of a mature epithelium this cell susceptibility is acquired often as a result of chronic irritation. When the cancerogenic factor is now added cancer is possible. In plant tumors this dual phenomenon—cell susceptibility and immediate agent (parasite)—is well seen.

An organism with a complex life story has been obtained almost constantly from cancer. It possesses yeast, coccal, bacillary, and amorphous phases, and each of these can grow true to type and live a wholly independent life. Evidence has been given that the parasite lives in symbiosis with the cancer cell in the amorphous phase, and it is from this that all the other ohases are derived during incubation of a cancerous growth. The discovery of this phase, it is claimed, provides the key to the cancer phenomena, as also the key to the morphological variants.

The morphological features of this parasite resemble the life story described by many writers for other classes of pathogenic organisms. There is now strong evidence to support the view that a similar morphological variability is common to all bacteria and that bacterial classification is in need of revision.

The parasite belongs to familiar bacteria which are wide spread in nature, and the ease with which cancer can b induced experimentally in animals by chronic irritation sug gests that tissue susceptibility wherever found implies th immediate risk of infection by a ubiquitous organism.

The free and universal exposure of man and animals t infection, combined with the (relatively) small proportio of the total which develop cancer, suggests the all im portance of cell susceptibility, and corresponds to th laboratory difficulties attendant on an attempt to produc cancer experimentally by the injection of organisms. Th marked proliferation of primitive tissues sometimes in duced in animals by the experimental injection of the car cer organism may resemble an ordinary infective proces while in an advanced case it stimulates a progressiv lymphoma or pseudo leucemia.

Isolation of the Glover Microorganism from Blood an Tissue of Carcinomatous Cases.—Julian Loudon an James M. McCormack (*The Journal of Cancer,* July, 1925 lay claim to having isolated the identical microorganisr from the blood of patients suffering from carcinoma of th lip, tongue, palate, stomach, colon, rectum, kidney, breas and uterus. The same microorganism has been isolate from primary and secondary carcinomatous tissue fro the breast, liver, ovary, omental glands, and glands of th neck. Similar or identical microorganisms could be cu tured from the tissues of carcinomatous mice. On all ex cept the Glover medium, the cancer microorganism assume the coccus form. Rigid aseptic precautions were used i every case. In each case controls were used, and in nor of these was any cultural growth obtained. Up to th present time the authors have been able to culture th Glover microorganism from the blood of every carcinoma tous patient investigated. All patients were fairly we advanced and the diagnosis was confirmed by several cor sultations. Hereafter they hope to produce additional ev dence to prove that the Glover microorganism is the onl agent in reference to carcinoma that fulfills Brand's postu late of universal applicability.

Etiology of Malignant New Growths.—W. E. Gy (*Lancet.* July 18, 1925) has made some investigations whic lead him to look upon cancer—using the term in its wide sense—as a specific disease caused by a virus (or group viruses). Under experimental conditions the virus alone ineffective; a second specific factor, obtained from tum extracts, ruptures the cell defences and enables the virus infect. Under natural conditions continued irritation tissues sets up a state under which infection can occu The connection between the specific factor of a tumor a an irritant remains to be investigated. Some of the rel tively unimportant "irritants" are known, such as coalta paraffin oils, etc. The virus probably lives and multiplies the cell and provokes the cell to continued multiplication.

The methods of experiment described, and the obvio extensions of them, give the means of classifying the viruse of investigating the nature of the specific factor, and testing suspected irritants, such as preservatives in fooc which may play an important part in the genesis of a tumc

Neuroepithelioma of the Spinal Cord.—J. A. Hertwe and L. D. Stevenson (*Annals of Surgery,* February, 192 report a case of interest on which they comment as follow It seems evident that in the face of the testimony of so mar observers a true diagnosis cannot be made until medulla symptoms appear. It is worthy of emphasis, however, th tumor formation in the posterior lateral region may be closely related to the posterior nerve roots that root pain the only symptom for considerable periods. The type tumor here studied, because of its soft texture, its point origin beneath the arachnoid, and its retention under th membrane, is particularly adapted to exerting the banef pressure on the roots.

So far it seems impossible to predict the nature of the tumors in the cord or brain before operation. When fou at operation they may have the most innocent appearan and be capable of rather easy removal. However, like th related tumors of the adrenal and retina, they are maligna with a tendency to form metastases in the neighborhood an potentially at least, distant metastases as well. It wou seem to be wise, therefore, to remove them with as litt disturbance of the tumor as possible and to realize th removal of any portion of them by curette or sharp disse tion may be followed by recurrence of the tumor with rapidly fatal result.

Radiation Therapy in Malignant Disease.—G. E. Pfahler (*Surgery, Gynecology and Obstetrics,* October, 1925) holds that preoperative irradiation will devitalize the cancer cell and prevent its transplantation or dissemination, while postoperative irradiation should destroy remaining carcinoma cells.

Thorough and skillful treatment by radiation offers most in all stages of carcinoma of the cervix. Sixty to eighty per cent may be expected to recover if treated in the earliest stages, while less than one per cent will recover in the late stages.

Radiation will not cure generally disseminated cancer. The more extensive the disease, the less the chance of recovery. Radiation is a local method of treatment.

Lessons Learned from Failures in the Röntgen Ray Treatment of Cutaneous Cancer.—Henry H. Hazen (*Journal of Cancer Research,* September, 1925) reports that a consideration of the facts observed would seem to indicate that the usual doses of the röntgen rays do not directly kill the cancer cells, but stimulate certain defensive reactions in the tissue. One of the defensive mechanisms is a local reaction, but there is good reason to believe that there may likewise be some general immune process concerning the nature of which we are still ignorant. From the practical standpoint preoperative radiation has a scientific basis. In treating cutaneous neoplasms by either the röntgen rays or radium, care should be taken that there be a fairly wide margin of normal tissue exposed in order that the defensive reaction be established. Cancer invading cartilage or scar tissue cannot be satisfactorily dealt with by irradiation.

Radium in Breast Cancers.—B. J. Lee and R. E. Herenden (*Annals of Surgery,* September, 1925) maintain from their study of a series of cases that preoperative and postoperative radiation are of value as an adjunct to surgery in the treatment of carcinoma of the breast. Best results are obtained when both are used. The basis for use of preoperative radiation depends partly upon clinical experience and partly upon histological evidence. The more malignant the tumor the more ready its response to radiation and the more extensive are its clinical evidences of regression. Clinical experience therefore strongly favors the use of radiation prior to operation to convert temporarily, at least, a growing tumor into a regressive one. The changes induced by radiation in the environment of the tumor also furnish a less favorable soil in which remaining tumor cells may grow, and renders dislodged cells less viable wherever they may be carried. Postoperative radiation is recommended because, even with the best surgical technic, dislodged tumor cells may be left in the operative field, or may have escaped removal.

The technic and doses of both preoperative and postoperative radiation as employed by the authors are presented.

Further Experience in Cancer of the Breast.—B. B. Davis (*Surgery, Gynecology and Obstetrics,* September, 1925) suggests a tentative grouping based on local condition and not on the duration of the disease, as follows:

Group I. The very early case. This will include those with a nodule, with no puckering of the skin, no fixation of any kind and no palpable glandular enlargement. Manifestly, this group will require exploratory incision and microscopic evidence to make the diagnosis. A high rate of recovery, eighty-five to ninety per cent., is to be expected in this group.

Group II. The early case. Here the preoperative diagnosis is more certain. There is some puckering of the skin, the outline of the mass is a little less definite, the perfect normality of the nighborhood tissues is not so easy to confirm; but there are no enlarged glands to be felt. The clinical and macroscopical examination will usually determine the diagnosis, but in some cases the microscope will be a necessary aid. The prognosis is still good but a little less favorable than that in Group I.

Group III. The midline case. In this group the diagnosis is still more apparent. The puckering of the skin is pronounced. Examination of the axilla may leave one in doubt. If the mass is centrally located, retraction of the nipple may be present. A fairly positive preoperative diagnosis can be made, and where the mass is cut across, it will show the characteristic cancer appearance. A good percentage of these cases should be cured by operation.

Group IV. The advanced case. One or more of the following conditions will be present: the skin will be sufficiently involved to move with the mass; there will be definite fixation to the deeper tissues; or a positive involvement of the axilla will be manifest. The prognosis is much worse and will be somewhat affected by the presence of one or two or all of the conditions named.

Group V. The very advanced case. This group includes cases the diagnosis of which may be made by the tyro. The mass is much fixed. There may be discoloration of the skin or even ulceration over the mass, and the axilla contains hard masses more or less fixed. The prognosis in this group will be bad; much worse than most have been led to believe.

Group VI. The inoperable case. Absolute fixation of the breast to the thoracic wall, carcinomatous thickening or nodules extending widely over the chest, extensive ulceration, a fixed mass in the axilla, a definite involvement of the supraclavicular glands, and more or less widespread metastases make the case eligible to this group. Any or all of these conditions render the case hopeless. Only palliative treatment is to be suggested for this group.

It is the author's opinion that as the results are studied, more and more of the cases in the "very advanced group" will be transferred to the "inoperable group." He says he is losing confidence in the value of surgery in the cases that already show widespread infiltration.

Varying Degrees of Malignancy in Cancer of the Breast.—Robert B. Breenough (*Journal of Cancer Research,* December, 1925) considers the several factors that enter into the determination of the degree of malignancy of cancer of the breast and summarizes them as follows:

1. The degree of malignancy of a given case of cancer of the breast can be determined with reasonable accuracy by study of the histology of the original tumor; and three classes, low, medium, and high malignancy, can be distinguished.

2. Such a classification is of importance in prognosis, and should be of assistance in estimating the value of therapeutic measures.

3. In estimating the degree of malignancy of a given tumor, the following factors are of importance:

a. Degree of differentiation as shown by arrangement of cells around an open gland lumen (adenocarcinoma).

b. Degree of secretory activity of cell protoplasm as shown by vacuoles and droplets of mucoid material.

c. Uniformity of size of cells and of nuclei, as opposed to variations in size.

d. Absence of presence of hyperchromatic changes in nucleus, and few or many mitotic figures, and whether irregular or not.

e. High malignancy is shown by cells and nuclei of irregular shape and size without secretory function, and arranged in solid columns, large or small, together with numerous and irregular mitoses and hyperchromatism. The extreme degree of these features is pleomorphism.

4. A high degree of round cell infiltration appears to indicate a considerable degree of cell degeneration, and is not to be relied upon as an indication of the resistance of the individual to the cancer growth.

5. Hyalinization of the stroma does not indicate active resistance to the tumor growth but is rather a factor of the age or previous condition of the mammary tissue in which the tumor lies.

Primary Sarcoma of the Spine.—S. Kleinberg (*Annals of Surgery,* February, 1925) presents a case first diagnosed as Pott's disease, of which he says: In this case and in a number of other tumors of the spine we did not find Bence-Jones bodies in the urine. I am inclined to the opinion that when this test is negative, it does not help us any, as the case may still be one of a tumor of the bones. This leads me to the conclusion that the test has no value unless it happens to be positive. In a similar case in the future the signs in order of importance which would incline one away from the diagnosis of Pott's disease and to that of a neoplasm are: 1, lack of destruction of the intervertebral discs; 2, rapid destruction of the vertebræ, and 3, early appearance of symptoms of a transverse cord lesion.

Embryoma of the Kidney.—G. B. Packard and A. Blumberg (*American Journal of Surgery,* December, 1924) so designate the mixed tumor of the kidney found in infancy because of its embryonal origin. Early operative removal should be the treatment. Operative mortality is high and increases with the duration of the tumor. Later, metastasis is the rule.

Medicolegal Notes.

ACCIDENTAL DEATH AND DEATH BY ACCIDENTAL MEANS

The Utah Supreme Court holds, Carter v. Standard Acc. Ins. Co., 238 Pac. 259, that there is no substantial distinction between the phrases "accidental death" and "death by accidental means" so as to preclude recovery under a policy covering death by "accidental means" for accidental death from an overdose of landanum, taken to induce sleep.

STATEMENTS MADE TO MEDICAL EXPERT AS RESULT OF HIS EXAMINATION HELD ADMISSIBLE

The Texas Commission of Appeals holds, Missouri Pac. Ry. Co. v. Baldwin, 273, S. W. 834, that statements of the plaintiff in a personal injury action made to a medical expert to whom he went for the purpose of making him a witness on his behalf, the statements being made in connection with and as a result of the examination made by the doctor, were admissible.

HERNIA HELD RESULT OF ACCIDENT

An employee was run into by a lumber truck which he was handling in the course of his employment. He was severely bruised in the abdominal region. There was a sudden onset of severe pain in the groin. There had been no previous symptoms of hernia, which developed immediately after the accident. There being no evidence to the contrary, the Minnesota Supreme Court held, Frederickson v. Burns Lumber Co., 204 N. W. 161, that the hernia was due to the impact of the truck, an accident arising out of and in the course of the claimant's employment.

CARE OF HOSPITAL FOR DELIRIOUS PATIENT

In an action against a hospital by a patient who while in delirium, climbed or fell from a third story window, sustaining serious injuries, the South Dakota Supreme Court, in Fetzer v. Aberdeen Clinic, 204 N. W. 364, aproved an instruction charging that no one is required to guard against or take measure to avert that which, under the circumstances is not likely to happen, or, more accurately, which a reasonably prudent person under the circumstances would not anticipate as likely to happen; that no man does or is required to take measures to avert dangers which the circumstances as known to him do not suggest as reasonably likely to happen; that these circumstances include the patient's mental condition and aberrations and what he is likely to do by reason thereof; that the fact that a patient may be delirious or not in control of his mental faculties is not sufficient to put the dependant hospital, its agents, servants or employees on their guard to prevent selfinflicted injury; that it is only when they have notice of conduct or language on the part of the patient evidently a hallucination or a purpose to inflict such injuries, and, in this case, unless the defendants, their agents, servants and employees had notice or knowledge of conduct or condition of mind on the part of the plaintiff which indicated that he intended selfinjury or selfdestruction, or intention to escape from the building, the plaintiff could not recover.

The burden was held to be on the plaintiff to show his own mental incapacity and also notice thereof to those sought to be charged; and this notice of the condition of the patient must be such as to give those sought to be charged reason to believe that his doing injury to himself may be anticipated. To hold hospitals, nurses, or physicians responsible for injuries which patients may inflict upon themselves, unless the patients have given evidence of the probable danger of such infliction of injury, would, it is held, be a harsh rule.

INSURANCE POLICY PROVISION REQUIRING PHYSICIAN'S WRITTEN REPORT EVERY THIRTY DAYS HELD VALID

The Texas Court of Civil Appeals holds, American Nat. Ins. Co. v. Burns, 273 S. W. 339, that there is nothing unreasonable in a provision of an accident policy requiring the insured who claims compensation for disability caused by injury or sickness which lasts longer than thirty days to keep the company informed of his condition by furnishing it with his physician's report every thirty days; such provision being manifestly made for the protection of the company against fraud and imposition. It is also held that the provision is not prohibited by V. S. Stat. 1914, art. 5714, providing that any stipulation fixing the time within which notice of claim for damages shall be given at a less period than ninety days shall be void.

INJURED EMPLOYEE ENTITLED TO SELECT HIS OWN DOCTOR

Although the general rule is that the employer who is called upon to pay the cost of medical services under the Workmen's Compensation Act has a right to select the doctor who shall treat the injured employee, the Michigan Supreme Court held, in Gardner v. Michigan Sugar Co., 231 Mich. 331, 204 N. W. 100, that under the facts and circumstances shown by the evidence, the claimant was warranted in securing the medical attendance of his family physician at the employer's expense. The employer's doctor was absent, and his brother, who looked after his patients, after one treatment, referred him to another doctor. Not satisfied with his progress under this doctor, the employee went to his family physician, the employer, on being notified of this, making no objection and tendering him no other medical service.

DEATH FOLLOWING DRINKING OF LIQUOR CONTAINING FUSEL OIL HELD NOT DEATH FROM ACCIDENTAL MEANS

In an action upon an accident policy the Iowa Supreme Court held, Calkins v. National Travelers' Ben. Assn. of Des Moines, 204 N. W. 406, that evidence that deceased had been a hard drinker and that, while drinking liquor consisting largely of fusel oil, he accidentally took more than he intended, was not sufficient to warrant a finding of death by accidental means. Fusel oil was defined as a volatile oil liquid obtained in the rectification of spirituous liquors made from the fermentation of grain, potatoes, the marc of grapes and other material. Its chief constituent, amyl alcohol, is described as a direct nerve poison. According to the testimony, fusel oil has a tendency to settle to the bottom of a vessel containing "hooch" manufactured from grain and potatoes.

HEALTH POLICIES

The insured under a health policy claimed indemnity under a paragraph in the policy providing for a stipulated rate during the time he was "necessarily, continuously and actually confined within the house." The trial court instructed the jury that the mere fact that the insured was able to walk from his house to the doctor's office, or take a railroad train to go to a hospital for treatment, did not in itself necessarily break the continuity of the confinement or the consecutiveness of the number of days he may have been confined to the house, within the meaning of the paragraph controlling indemnity for confining illness. The North Dakota Supreme Court held, Jentz v. National Casualty Co., 204, N. W. 344, that, under the evidence, the instruction was not erroneous.

It was also held, under the evidence, that the disease known as torticollis does not, as a matter of law, result wholly or in part from rheumatism, and that the liability of the insurer to an insured suffering from torticollis was not necessarily controlled by the policy paragraph regarding chronic diseases.

The Danger of Infection Following Operations Where the Eyeball Is Opened

*With a Report of Fifteen Hundred Successful Major Operations Performed According to the Author's Method**

GEORGE HUSTON BELL, M.D., F.A.C.S.

New York

The danger of infection in cataract operations is ever present until the healing process is complete. All investigators have agreed that postoperative infection in modern eye surgery, with rare exceptions, has its origin in the conjunctival sac; since we cannot sterilize the cul-de-sac, then we must do the next best thing. My method makes war on the saprophytes of the conjunctival sac and the cornea, which are the organisms responsible for primary infection. In my first paper (1) read before the American Medical Association in 1921, my technic was outlined and since then has been changed to the extent that we now use argyrol more freely than formerly.

In no case of our fifteen hundred operations did we wait for a single day before operating to clean up whatever was found in the smear from the conjunctival cul-de-sac. Much valuable time is lost by trying to clean up the conjunctiva when there is a questionable smear. The time that is lost is due to inadequacy of hospital facilities and also to patients. According to my method, we do away with all of this lost motion. If a patient's eye looks clinically clean, we go ahead and operate regardless of the findings in the smear. The socalled senile cataracts are not looked upon as clinically unclean by us, but we do exert pressure over the lacrimal sac in such a way as to cause the smallest quantity of fluid present in the sac to flow back through the canaliculi. Cases of mild infection limited to the sac will thus be detected and must be cleared up before we regard the eye as clinically clean. In other words, we pay no attention to the findings of the bacteriologist.

I have such strong faith in the silver and argyrol treatment that I am anxious for all ophthalmic surgeons to give it fair trial, and it gives me great pleasure to state that Professor Lindner of Vienna is using my method now as regular routine in his clinic.

TECHNIC

First step.—The focal infections, such as oral sepsis, diseased tonsils, and toxemias of the intestinal tract, must be removed. I hold that it is just as necessary for the ophthalmic surgeon to "get his house in order" before subjecting his patient to a major operation upon the eye, as it is for the general surgeon to clean house. Every patient of mine, whether clinical or private, must stand the acid test for the "three T's" (2)—teeth, tonsils and toxemia—before we even consider the operation. This routine is carried on in my clinics at the New York Eye and Ear Infirmary, the New York Polyclinic Hospital, Hudson Street Hospital and Marine Hospital, also in my private practice. At the annual meeting of the A. M. A. held in 1919 I said (2) that a dirty mouth was one of the greatest menaces to the human race. I wish now to reaffirm and confirm that statement. We must make no mistake about oral sepsis, as it is the arch enemy of the ophthalmic surgeon. The germs themselves and toxins or their poisonous products must be eliminated from the system as far as lies in our power, if we are to better our cataract results. In this way, we can hope to reduce the amount of secondary postoperative infections. If we clean the blood by getting rid of toxemia, then we will raise the resistance of our patients, so that we can approach the operation with a confidence and courage such as we have not had in the past.

We must bear in mind that the longer toxemia exists, the less nerve energy and resistance there is.

All of this work on focal infections must be done from two to three months beore the patient is admitted to the hospital. We lay great stress on this work, as we must study the general condition of patients more than we have done in the past. A Wassermann test is made in zonular and complicated cataracts, also in all senile and juvenile cataracts. The urine is examined several times previous to the operation, and the height of blood pressure must be known.

Second step.—The patient is then admitted to the hospital. Twenty-four hours before the operation a dose of castor oil is given, as nothing sweeps and cleans the intestinal tract like castor oil. It has been the standby of physicians since time immemorial; I know of no substitute for it.

*Read at the Sixty-first Annual Meeting of the American Ophthalmological Society, Washington, D. C., May 5, 1925.

Copyright, 1926, by A. R. Elliott Publishing Company.

Third step.—One hour before the operation a smear of the conjunctival sac is taken, after which two drops of a one per cent. solution (five grains to an ounce of distilled water) of silver nitrate are instilled into each eye. The silver produces an irritation, but not an inflammation, so that when the patient comes to the operating table the eyes look red and inflamed, with a certain amount of mucus at the inner corners. The brow, the eyelids, and adjacent skin are washed thoroughly with castile soap and water, and the eyes are then washed out with a normal salt solution as a means of freeing the operating field of mucus, dust, etc. While the eye is undergoing cocainization it is bathed continually in a twenty-five per cent. solution of fresh argyrol. In other words, every time a drop of cocaine solution is used in the eye, a drop of twenty-five per cent. solution of argyrol is instilled. The slogan is "drop for drop." We have been using novocaine (two per cent. solution) paralysis of the orbicularis as a routine for the last four years, and regard it as a great advance in the technic of extraction.

Recently for paralyzing the eyelids, we have followed Robinson's (3) technic and have found it most efficacious. Also it is imperative to have your assistants wear sterile rubber gloves. After the patient is well under the local anesthesia, the operation is performed. We always try to get a large conjunctival flap, after which we now use as a part of our regular routine Berens's (4) untied suture in senile and juvenile cataracts. Our usual technic is then employed. Afterwards we use two drops of three per cent. solution of atropine, and twenty-five per cent. solution of argyrol, after which both eyes are bandaged for forty-eight hours. The bandage is then removed and the eyes are dressed. One drop of three per cent. solution of atropine and one drop of twenty-five per cent. solution of fresh argyrol are instilled into the operated eye. At this first dressing (forty-eight hours after the operation) the patient is given the use of the unoperated eye and only the operated eye is bandaged. Also, the patient at this first dressing is allowed to sit up in a chair. Freeing the unoperated eye of a bandage as soon as possible helps to prevent socalled cataract delirium. At the end of four days the dressing is left off entirely and only a cataract mask is worn. Generally atropine is stopped at the end of four days, but twenty five per cent. solution of fresh argyrol is now used three times a day, until the patient leaves the hospital.

OPERATIONS PERFORMED IN FIFTEEN HUNDRED CASES OF INTRAOCULAR DISEASE.

No. of Cases	*Diagnosis*	*Smear*	*Operation*
10	Chronic glaucoma	Pus, mucus, large diplococci	Lagrange
145	Immature and mature senile cataracts	Negative	Prelim. iridectomy
50	Mature senile cataracts	Epithelium, K.L.B.	Prelim. iridectomy
125	Mature senile cataracts	Leucocytes, large and small diplococci	Prelim. iridectomy
75	Mature senile cataracts	Pus, leucocytes and mucus	Prelim. iridectomy
55	Glaucoma	Negative	Iridectomy
25	Acute glaucoma	Pus, pneumococci, mucus	Iridectomy
25	Old iritis	Mucus, leucocytes, no bacteria	Iridectomy
20	Occluded pupil	Negative	Iridectomy
10	Anterior synechiæ	Negative	Iridectomy
30	Chronic glaucoma	Negative	Lagrange
5	High myopia	Negative	Linear extraction
20	Chronic glaucoma	Pus cells, mucus	Trephine
15	Capsular cataracts	Occasional diplococci	DeWecker's
15	Secondary cataracts	Pus cells, mucus, bacteria	DeWecker's
10	Postpolar cataracts	Mixed germs, diplococci	Discission
20	Zonular cataracts	Negative	Discission
10	Zonular cataracts	Pus cells, mucus, bacteria	Discission
30	Secondary cataracts	Negative	Discission
30	Secondary cataracts	Mucus, leucocytes	Discission
5	Buphthalmia	Leucocytes, large diplococci	Iridectomy
20	Traumatic cataracts	Negative	Linear extraction
10	Traumatic cataracts	Leucocytes, cocci	Linear extraction
10	Juvenile	Xerosis and diplococci	Linear extraction
10	Zonular cataracts	Negative	Linear extraction
20	Traumatic cataracts	Small, large diplococci	Linear extraction
20	Congenital cataracts	Negative	Linear extraction
5	Morgagnian cataracts	Mucus, pus, diplococci	Extraction
170	Mature senile cataracts	Negative	Extraction
25	Mature senile cataracts	Pus cells, no bacteria	Extraction
75	Mature senile cataracts	Leucocytes, occasional coccus	Extraction
10	Mature senile cataracts	Mucus, bacteria, leucocytes	Extraction
30	Mature senile cataracts	Epithelium, pseudo K. L. B.	Extraction
20	Mature senile cataracts	Much mucus, no bacteria	Extraction
20	Mature senile cataracts	Mucus, diplococci, pus cells	Extraction
40	Mature senile cataracts	Leucocytes, no bacteria	Extraction
40	Mature senile cataracts	Mucus, staphylococci	Extraction
50	Mature senile cataracts	Pus, pneumococci, mucus	Extraction
5	Mature senile cataracts	Mucus, leucocytes, no bacteria	Extraction
10	Mature senile cataracts	Mucus, few cocci, no pus	Extraction
20	Mature senile cataracts	Leucocytes, large and small diplococci	Extraction
20	Mature senile cataracts	Pus, mucus, leucocytes	Extraction
20	Mature senile cataracts	Mucus, large and small diplococci	Extraction
20	Dislocated lens	Mucus, leucocytes, bacteria	Extraction
30	Complicated cataracts	Pus cells, mucus, bacteria	Extraction
14	Cyst of iris	Negative	Iridectomy
6	Detachment of retina	Negative	Trephine
50	Mature senile cataracts	Xerosis and diplococci	Extraction

SUMMARY

If we are to improve our cataract results and have fewer postoperative infections, we must "start at the bottom and not at the top." It is just as necessary for the ophthalmic surgeon to "clean house," as it is for the general surgeon.

1. The arch enemy of the ophthalmic surgeon is oral sepsis. Patients must stand the acid test for focal infections, the "three T's" (teeth, tonsils and toxemia), before we will consider the operation. This applies to all patients except emergency cases. Wells, before the New England Dental Society, called attention, in no uncertain manner, to the importance of going after oral and focal infections before attempting operations where the eyeball is opened.

2. We wish to express strong faith in silver nitrate and argyrol as germicides and irritants. In all of these fifteen hundred cases, one per cent. silver nitrate was instilled into the eye one hour before the operation, and twenty-five per cent. solution of argyrol was used at the time of operation; in fact, the eye was bathed in argyrol during cocainization.

3. In analyzing our fifteen hundred cases, we have three secondary infections coming on nine days after the operation. One of these patients recovered and has fifty per cent. vision; chronic iridocyclitis developed in the other two. These patients had negative smears. We were able to trace these infections to faulty technic in reference to oral sepsis.

4. Cases I and II occurred in the same patient.

His smear showed pus and diplococci, mucus; there was also chronic dacryocystitis. The patient had chronic glaucoma with very little vision. I performed a Lagrange operation without bringing the tension down; in two weeks, another Lagrange operation was performed. No infection followed either of these operations. Doctor Stout was house surgeon at the time and assisted.

5. Vitreous humor was lost in twenty cataract cases. In Case No. 55, a bead of vitreous humor appeared. The smear contained pus and a number of diplococci. No infection resulted. Case No. 167 was a bad case of ozena; smear showed pus cells and staphylococci. There was no infection. An iridectomy was performed in Case No. 280, after which a secondary membrane was removed. Some vitreous was last; smear showed considerable mucus and a few leucocytes and occasional diplococcus. There was no infection. In Case No. 391, an iridectomy and capsulectomy were performed; Vitreous was lost; the smear showed pus, diplococci and mucus and no infection resulted. Case No. 518 presented a dislocated lens. Iridectomy and extraction of the lens were performed; considerable vitreous was lost in this case; the smear showed a few leucocytes and some bacteria—no infection resulted. In Case No. 799, there was ozena; smear showed lecocytes and large diplococci—no infection resulted. In Case No. 897, the patient squeezed and lost considerable vitreous. The smear showed epithelium and pseudo K. L. B.—no infection resulted.

6. Case No. 1150.—Mr. H., aged sixty-eight, with mature senile cataract, was referred to me by Dr. Emil Mayer. This patient had been troubled for years with an obstruction of the nasal duct. Probes had been passed into the duct from time to time. The canaliculi were still open, but no pus could be squeezed out of the sac. He had angina pectoris and would not submit to extirpation of sac. Dr. Mayer and I decided to undertake the extraction of the cataract with an extra dose of silver. One per cent. silver nitrate solution was used in his eye at 9 a.m. and again at 12 o'clock and the eye was bathed in argyrol at the time of cocainization. At 2 p.m. the operation was performed, the patient sitting up in a chair on account of his heart. His eye was dressed every twenty-four hours on account of his lacrimal trouble. He got a beautiful eye with 20/20 vision. The smear in his case, before the silver was instilled, showed pus cells, diplococcoci and mucus. But for its "watery" condition, the eye looked clinically clean. Dr. Robb was house surgeon on my division at the infirmary and assisted me in this operation.

Case No. 1200 was a similar case in a woman, aged sixty, with lacrimal trouble of long duration. Her smear was negative and her eye looked clinically clean. I operated upon her as I did on Mr. H., using silver nitrate one per cent at 9 a.m., and again at 12 o'clock, and extracting the cataract at 2 p. m. Her eye was also dressed every day. Halpert was house surgeon at the time and assisted me.

Case No. 1450 was Dr. Vandegrift's case. Briefly, it was a cataract case with chronic trachoma; smear showed pus and diplococci. In this case one per cent. silver was used for three days previous to the operation; at the time of the operation the smear was free from pus cells but showed diplococci; the cataract was removed by Dr. Vandegrift; no infection. This was the only eye the patient had. Four weeks later, on account of soft lens substance remaining, Vandegrift opened this eye again with a keratome and washed out the débris, using my method before operation; no infection followed and patient now has 20/70 vision.

I mention Cases No. 1, 2, 1150, 1200 and 1450 especially to prove to you the great power silver nitrate and twenty-five per cent. solution of argyrol have as practical specifics against infection. Of course, I am not advocating operating upon every cataract case that comes along in which the patient has serious trouble with the lacrimal apparatus without first performing an excision of the sac. But I do think, if the eye looks clinically clean and no fluid or secretion can be squeezed out of the sac, and one per cent. silver nitrate is used twice in the eye, and at four hour intervals, and the eye bathed in argyrol at the time of the operation, it is perfectly safe to operate. Investigations made by Elschnig and Lindner have proved that in the great majority of cases the conjunctival sac contains the pathogenic organisms, and with proper technic, all other sources of infection can be excluded.

7. In juvenile and lamellar cataracts, we perform a peripheral linear incision with a conjunctival flap just back of the limbus. Also in all discissions, we enter the anterior chamber through the conjunctiva and sclera, just back of the limbus. The same rule applies to senile cataracts; we make the section in the sclera just behind the limbus, always having in mind a conjunctival flap. We consider it obsolete to go through the cornea in performing discissions on zonular, juvenile and capsular cataracts. Why attack the eye at its weakest point? The chances for infection are greatly increased by using the corneal route. Lindner (5) has shown that pneumococci are often present on the cornea of both the old and the young and calls attention to the relatively greater incidence of infection in discission operations done through the cornea. The last statistics, in the literature on this point, given by Asmus of Berlin, showed an infection percentage of five per cent. for corneal discissions and for discissions through the sclera, a percentage of 0.3 per cent. in two hundred and ninety five cases.

8. In our list of fifteen hundred cases we operated upon six hundred and ten senile cataracts, ninety soft cataracts and thirty complicated cataracts, making all told seven hundred and thirty cataracts removed, with two eyes lost from secondary infections coming on nine days after the operation. Not a single case of primary infection or panophthalmitis resulted. In the last eleven hundred intraocular cases in which operation was performed, we have not had even a single late infection. We performed one hundred and twenty-five discissions on soft and secondary cataracts, five hundred and thirty iridectomies, forty Lagrange and twenty-six trephine operations, thirty DeWecker and twenty-four miscellaneous operations without infection. It is interesting to note that the ages of our patients ranged from two months to ninety years. Twelve of our patients with cataract had three per cent. sugar in the urine. Sugar is no barrier to the operation unless it exceeds four per cent.

Duane (6) in speaking of my method, calls it "artificial preoperative leucocytosis" and he further adds: "The good results obtained by this practice in the eye operations seem well substantiated by statistics and the translator believes that it is based on sound theory."

ACTION OF SILVER NITRATE AND ARGYROL

Lindner (5) has the following to say: "The mechanical removal of the dead or degenerated surface epithelium is facilitated by preoperative instillation of silver nitrate, while the postoperative instillation of fresh argyrol inhibits the growth of microorganisms in the first twenty-four hours." In other words, the argyrol "carries on" the work which was begun by the silver nitrate. They go hand in hand in making war on the saprophytes of the conjunctival sac and the cornea which are the organisms responsible for intraocular infections. Also, argyrol is especially good to prevent low grade septic invasion through a wound kept open by a prolapse of vitreous.

I know that silver nitrate and argyrol furnish a marked degree of stimulation to the conjunctiva and in that way leucocytosis is produced. They promote phagocytosis and the formation of antibodies, and in this way put the tissues into a stronger state of defense against the invasion of microorganisms. Even were an inflammation produced by the silver and argyrol, it would only diminish the probability of infection, not increase it, because the leucocytes and their leucins are valuable aids in combating bacteria. And what makes the phagocytes so active? It is the preoperative removal of foci of infection—going after the "three T's."

The thought has occurred, however, that this preventive effect of the silver salt may be, at least in part, due to the germicidal action of the silver, and in order to shed more light on the subject a series of fifty cases have been investigated by Dr. S. P. Oast and Mr. E. B. Burchell in the laboratory of the New York Eye and Ear Infirmary.

The following technic was employed on the patients admitted to the infirmary: A culture was taken from the conjunctiva; then several drops of freshly prepared silver nitrate in one per cent. solution were instilled into the lower conjunctival cul-de-sac, and the eye left unprotected by a dressing of any sort; after a lapse of two hours, just before the operation, a culture was again taken in the same manner.

The material was collected by means of a small platinum loop from the lower conjunctival cul-de-sac,

BACTERIOLOGICAL STUDIES

No. of cases examined	*Before*	*After*
Three	Diplococci	No growth
Three	Diplococci and xerosis	No growth
Four	Xerosis	No growth
Five	Staphylococcus	No growth
One	Subtilis bacillus	Staphylococci
One	Xerosis and diplococci	Xerosis and diplococci
Four	Staphylococcus	Staphylococcus
One	Xerosis and staphylococcus	No growth
One	Xerosis	No growth
One	Streptococcus and staphylococcus	Staphylococcus
One	Xerosis	Xerosis
No growth	No growth	No growth

care being taken to avoid contamination with the lids and cilia. This was transferred after the usual manner to agar starch which was incubated at 37° C. for twenty-four hours and then examined.

In the present series, in cultures taken two hours after the use of silver, in every case, a point was made of obtaining some of the stringy purulentlike masses such as are familiar to all who have observed the effect of silver solution in the eye, and it was extremely interesting to observe that the cultures obtained in this way invariably yielded no growth, or a considerably diminished number of colonies. In addition to argyrol and silver being powerful bactericides, I am strongly of the opinion that they increase the phagocytic power of body cells in and around the eye, producing a leucocytosis and leaving the eye protected during the healing process.

PREPARATION OF THE SILVER AND THE ARGYROL

The one per cent. solution of silver nitrate (five grains to one ounce distilled water) should be made up fresh at least every three months, and must be kept in a dark glass stoppered bottle. The rays of light cause the silver solution to become inert, and for that reason it should also be kept in a dark room.

The twenty-five per cent. solution of argyrol must be made up fresh for each operation. Unless you have a very reliable chemist, it is better for the surgeon to make up the argyrol solution himself.

Professor P. Knapp (7) makes several observations concerning the use of silver nitrate. First, he refers to the instillation of one per cent. to two per cent. nitrate immediately before the operation. The point of using the silver two hours before the operation, which is most important, he has overlooked. The two hour interval gives the silver time to destroy bacteria and produce a leucocytosis.

His second objection is that the silver increases secretion with many bacteria. Our research work at the New York Eye and Ear Infirmary shows that the silver does increase the secretion but cultures of the stringy, purulent like masses showed that they invariably yielded no growth or a considerably diminished number of colonies. In other words, two hours after the instillation of the one per cent. silver nitrate in the eye, cultures from the secretion of cul-de-sac showed the absence of the bacteria in eighty-two per cent. of the cases, whereas, before the silver was instilled, the cultures were positive in sixty per cent. of the cases. If Professor Knapp will use my method with an open mind, I feel that he will be pleased with the results. Certainly the clinical results are overwhelming.

I want to express my thanks to the house staff of the infirmary for their cooperation and assistance, and to express my thanks and great appreciation to Oast and Burchell for their excellent research word.

In addition to these fifteen hundred cases, R. C. Heflebower, of Cincinnati, reports five hundred intraocular operations performed according to my method without a single primary or secondary infection. Heflebower feels such a sense of security with the silver nitrate that he now no longer takes smears or cultures, reliance being placed in the efficacy of the preparatory treatment, and he adds, "The results have been most happy."

PRELIMINARY IRIDECTOMY IS OF PRIME IMPORTANCE IN ALL CATARACT OPERATIONS

1. It is much safer for the patient's eye and better for the surgeon in the long run.

2. It protects the eye and leaves it stronger for the years to come.

3. If it is the safe procedure when a patient has one eye, why is it not a good thing when he has two?

4. Doing preliminary iridectomies in my clinics and in my private practice have become a hard and fast rule with me. This rule applies to all cataracts. It enables me with safety to the eye to do all my operations just back of the limbus. I feel that it is a great mistake to use the corneal route in doing operations where the eyeball is opened.

5. Some operators and a few patients raise the objection to iridectomy on account of the necessity of making two trips to the hospital and because the danger of infection is doubled.

W. F. Hardy (8) says, and he is quite correct, that the operator raises these objections in his own mind much oftener than does the patient, and he adds, "If an ophthalmologist is thoroughly convinced that a certain line of action is the correct one, he will have little trouble in putting that conviction over to the patient and gaining his consent." As far as the extra chance for infection is concerned, we feel that we have been able to eliminate that argument.

6. We agree with Darrier and Hardy who are strong advocates of preliminary iridectomy.

7. I firmly believe that postoperative infection in the eye surgery is a preventable disease.

8. If you want every cataract operation to be successful, then use my technic, and a preliminary iridectomy. I hold and believe that it is the only way to get a good surgical result in every case. These are the conclusions that I have reached after doing cataract work for over twenty years.

Acute Infectious Mononucleosis*

EDWARD STEINFIELD, M.D.
and SAMUEL GOLDBERG, M.D.
Philadelphia

There is some evidence to indicate that the disease described by Pfeiffer (1) as glandular fever is in many respects analogous to the infection described by Sprunt and Evans (2) and by Blaedorn and Houghton (3) as benign lymphoblastosis. The infection was described by Longcope (4), who cited ten cases and gave a comprehensive review of the literature up to 1922. Though this condition is ordinarily regarded as moderately rare—at least in adolescents and adults—there appeared to be a greater prevalence of the infection in Philadelphia during the spring and summer of 1924. Of six cases noted in adults and adolescents, we have selected one which was observed at greater length and which presented most of the characteristic features of the disease. The descriptions by the authors cited above cover the subject thoroughly and a brief outline of the clinical course will here suffice.
